The statistical report prepared by the Committee on the Prevention of Tuberculosis in New York City, gives a high mortality for musicians, but I am told by the statistician that the figures include all sorts of musicians—opera singers, piano teachers, organ grinders, etc. There were, in fact, only seventy-one of all descriptions.

While the figures of Chalmers in England may include a larger number of persons, they likewise embrace such a heterogeneous mixture and are valueless for the purpose of this article.

4. Do you know of any cases of tuberculosis or other lung trouble that have apparently been helped by such exercise?

My medical correspondents say they have not known of such cases. Dr. Knopf writes: "Since blowing a wind instrument for the purpose of producing sound does not correspond to physiological breathing, the inspiration being short and the expiration being prolonged and forced, which is pathogenic and almost pathognomic of pulmonary tuberculosis, I cannot conceive how continued playing on such instruments can be of therapeutic benefit in pulmonary troubles." More than half the musicians have written that they know personally of cases of tuberculosis which have apparently been helped, or of persons with weak lungs who have taken up the study of a wind instrument at the suggestion of a physician, and who have been undoubtedly benefited.

Without giving the entire list of such cases, it may be interesting to quote from a letter from C. A. Lanier in reference to his brother, Sidney Lanier, who was no less distinguished as a musician than as a man of letters: "He did not deem himself a consumptive until after the war, during which he was a prisoner at a bleak point of confinement. . . He thought that regular exercise of breathing into most wind instruments would be helpful and strengthening to most lungs. He thought that women, especially, should play the flute. . . . His first hemorrhage came at 25, and he lived to be 39. He continued to play until his last year."

M. Lavignac, in answering this question, says that the emphysematous can be helped by vocal exercises or playing on wind instruments. (L'emphysémateuse peut etre amélioré par l'exercise vocal ou le jeu de l'instrument à vent.)

5. Have you known any bad results directly attributable to such exercise?

The unanimous answer is "none whatever."

6. Are they more or less subject to heart disease?

All replies from physicians are to the effect that they are neither more nor less subject to heart lesions. Of the musicians most of them say that they have never known a case of heart trouble.

7. What instruments seem most helpful or detrimental?

Dr. Knopf writes: "To the strongly developed individual, the moderate playing of any musical instrument, in relatively sanitary environments, I do not consider detrimental. I know of no wind instruments helpful therapeutically or prophylactically in diseases of the respiratory organs."

A majority of the answers from musicians give the larger brass instruments and the flute as the more beneficial; while the oboe is placed first among those which may possibly be detrimental, with the bassoon and horn in the same class.

The following statistics of the wind instrument performers of the Boston Symphony Orchestra have been secured through the kindness of Mr. Arthur Brooke of that organization. They are of interest as showing the general health of such musicians. The rehearsals and concerts of this orchestra number about two hundred and fifty for the year. On so many, he says, the

	Times Absent.	*Number of Seasons.*
First flute	3	9
Second flute	4	7
Third flute	[illegible]	22
First oboe	4	5
English horn	[illegible]	18
Second French horn	0	20
Third horn	[illegible]	14
Fourth horn (over sixty years)	0	24
First trumpet	4	5
Second trumpet	[illegible]	15
First trombone	few	18

This gives an average absence of less than two times in ten seasons of two hundred and fifty days each, or two times for twenty-five hundred days.

Literature.—In works on general medicine, I have found nothing bearing on this theme save in connection with the subject of emphysema. The following suggestion for those suffering from tuberculosis is from a most intelligent layman—Sidney Lanier: "The expansion of the lungs is of the greatest importance in removing congestion and preventing hemorrhage. . . A habit of this sort (of deep breathing) once acquired will soon develop a comfortable feeling in the chest and a freedom from oppression quite astonishing in view of the simplicity of the means used. The process itself is a better expectorant than any known to the pharmacopœia, and often has more efficacy in relieving the dreadful hack of the consumptive than all the drugs that can be administered without any of their injurious accompaniments. This gentle and constant expansion of the vesicles of the lung cannot be overestimated. every means should be devised to remind oneself of it and even to make it pleasant. The latter has been accomplished with great efficiency by playing the Boehm flute. The operation of playing the flute—so far as it depends on the breath—involves the precise motion of the lungs, which is of benefit to the consumptive, to wit, a full inspiration (always take care not too full, not straining in the least) succeeded by a slow and gentle delivery of the breath. * * * the least sign of fatigue should be the signal for stopping until the next day. . . The recommendation of flute playing to consumptives will seem strange to some, and possibly there may be physicians who would oppose it. It has, however, been long known as beneficial. Quantz, the flute player to Frederick the Great, speaks particularly of its value in this behalf. Perhaps it may be proper to add that this author knows positively and personally of most signal benefits resulting therefrom." ("Advice to Consumptives in Florida," pp. 213, 214).

In Burq ("Congrès International D'Hygiene," Tome 2, No. 10, p. 408) I found this summary of a study of the subject made by the above congress in 1879. "Conclusions: (1) That all the exercises of the respiratory organs, when they are done with moderation, and always according to the laws of reasonable gymnastics of the lungs, when they take place mechanically with fatigue (either mental or physical) and if nothing prevents free pulmonary expansion, are eminently salutary, and in this capacity ought early to enter into the hygienic of all persons more or less threatened with (I do not say already attacked by) pulmonary tuberculosis.

E (2) That the professions of singing and of music, above all the playing upon of wind instruments, exercised wisely by delicate persons, it goes without saying, can only be an excellent prevention of pulmonary consumption. I have mentioned wind instruments especially, because their playing naturally excludes dramatic passion, and other causes which, with song artists in particular, too often tend to destroy the good effects of the vocal exercises."

Review and Conclusions.—The use or disuse of function determines the development or decay of the organ which functionates. It follows from this law that insufficient breathing—incomplete expansion of the lungs—is a factor in lowering the vitality of the whole body, and especially of the lung tissues and in rendering those tissues more susceptible to bacterial invasion If the effects are as believed, then deep breathing exercise must not only serve to develop the chest and give more room for the organs of circulation and respiration, but it must also serve as a prophylactic measure of importance in bronchial and lung affections. Deep breathing has often been recommended for those inclined to such conditions. The difficulty of getting persons to carry out such exercise with patience and persistence is overcome when a wind instrument is breathed into. Besides the pleasureableness which causes the person to continue the exercise, there is an absence of the attendant evil of self-consciousness—of "condensed imagination." Notwithstanding exposure, and perhaps alcoholism, professional musicians would seem, from the data I have been able to collect, to be less subject to catarrhal affections.

As regards pneumonia, they would seem to be not more nor less subject to the disease. (The only case I have known followed extreme exposure in other work).

As regards emphysema, there is no good evidence that playing upon wind instruments is ever a primary cause. Where degenerative changes in the lung tissue have been brought about through some hereditary tendency, alcoholism or other condition, the process may perhaps be hastened by such forced expiration, but it occurs only with those performers who must develop an extreme degree of pressure within the lungs. Heart disease seems to be not more frequent among musicians than with persons of other callings. The few instances given are among those performers who must develop great pressure within the lungs.

In considering the effects with regard to tuberculosis, we may consider first the

Effects on the Non-Tuberculous of Robust Constitution.—There seems to be no evidence that there is anything in the exercise of playing on wind instruments which predisposes to infection, and, on the other hand, there could not be expected to be any prophylactic effect upon lung tissue already up to a normal standard. From the statistics of the German army, we gather that musicians of robust constitution are not more subject to tuberculosis than men of any other occupation of similar sanitary conditions.

In the case of the *Non-Tuberculous with Hereditary or other Predisposition,* the limitations of hereditary physical endurance and capacity for development must not be overlooked, and the

antitoxic insufficiency of the tissues, which seems to be a part of the inherited condition, should be taken into account. Persons of the diathesis, being often less vigorous, are inclined to avoid the sports of those who possess the average of vitality.

The general condition of such persons can be proved by general physical development, and is widely believed. Also that the lowered vitality of the lung tissues may be improved by a more complete use of the lungs is as widely held. Deep breathing exercises and singing have been highly recommended as prophylactic measures, and we can certainly class with these the blowing upon wind instruments. The players of wind instruments have no thought of "doing breathing exercises," and, besides, have the exhilaration which comes from an enjoyable exercise.

Persons of a tuberculous tendency often have a voice which gives them little pleasure in singing, and for such a wind instrument offers a sound-producing apparatus as perfect as that which might be used by the most robust instrumentalist. The effort required for some instruments, when the volume of tone is considered, is not greater than that of singing, while for the flute it is much less.

In professional work, both singing and playing become more taxing from the length of time which must be spent in the exercise and the greater volume of tone required. Flute playing is the only exception to the demand for greater force. Besides the demands on strength and endurance, the surroundings of professional musicians are often far from ideal.

Briefly, then, for persons inclined by physique or inheritance to tuberculosis, blowing on wind instruments presents a pleasurable exercise tending to expand the lungs and develop the chest, with accompanying good effects upon the circulation and digestion. The instruments used should be those in which the breath is not too much forced or withheld, and which require muscular exertion and a depth of breathing compatible with the physique of the performer.

That development of the chest and lungs does follow such exercise, when wisely carried on, seems borne out by my correspondence, by the literature quoted, and by a former investigation of the subject. The limitations of heredity as to possible physical development in persons of this type should not be overlooked, and they should be discouraged from adopting music with the expectation of finding in it an easy means to a livelihood, or with the anticipation of reaching a top round in the professional ladder.

For the Tuberculous it would seem that the breathing of the exercise under consideration is never injurious so far as the local condition is concerned, and in tending to expand unused or collapsed portions of the lungs and influencing the circulation in those regions might be of some benefit. The pneumatic cabinet, which has found considerable favor in the treatment of the disease, simulates in its respiratory effects somewhat the expiration of this exercise. In this machine, however, the inspiration is wholly passive, the atmospheric pressure on the whole body outside the alveoli being reduced. The expiration, however, is against pressure inside the alveoli sometimes as much as 50 mm. Hg.

The organism which has contracted tuberculosis may be compared to a ship which has sprung a leak. The inflowing water should not only be pumped out and the leak repaired, but it is also wise at the same time to lighten the burden of the vessel by getting rid of superfluous cargo. In the diseased we should endeavor to aid the local reparative process, but at the same time should not forget to diminish to a minimum the general wear and tear. While the exercise in its special effects seems to be comparable to an aid in checking the leak in the ship, may it not at the same time, through the muscular exertion which goes with it, add an additional burden to the general economy, and so neutralize local effects for good? Herein lies the danger. That the exercise is pleasurable, while making it the more beneficial to the normal organism, adds to the danger for the tuberculous. We have already noted the muscular effort required by some instruments when used in military bands and large orchestras. Of course, this effort is not long continued, and is hardly to be compared in laboriousness with most occupations. In those organizations requiring a less volume of tone, the theater pit and dance hall offer most vicious surroundings, even if the work be not fatiguing. The amateur is not bound to any hours of work nor to bad hygiene, and the only danger which besets him lies in overdoing, or in ensemble playing under bad conditions of ventilation or of dust.

Where the quality or quantity of his work then seems to make too great demands on his general vitality, the professional musician who has contracted tuberculosis would best adopt some less taxing work, and where his surroundings are bad he should find a place entailing less danger from added infection. The amateur should shun ensemble playing in bad surroundings, and should avoid carrying the exercise to the point of fatigue. Musicians having the disease should be made aware that they may spread the infection by allowing others to use the mouthpieces of their instruments.

Since in the first steps in learning to play an instrument much effort is wasted in producing the tones, it would seem unwise for one in whom tuberculosis had progressed to take up the exercise, as the pleasure would be slight as compared with the fatigue which might be entailed.

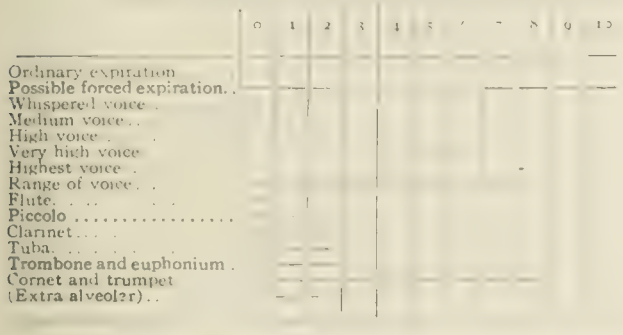
The instrument par excellence is the flute, especially the Boehm flute, since it offers less effort than the other instruments, and less even than singing; requires less skill in the production of tone than the reed instruments; is adapted for individual playing; is possessed of beauty of tone; is not somber; has a mechanism easily acquired, though always offering something to overcome in perfection of technique; and, lastly, is an instrument adapted for women as well as men. Of the other most used instruments, probably the soprano saxophone comes next in ease of blowing and manipulation, though it does not offer the same beauty of tone. The clarinet, while an especially interesting instrument, requires much more study, and, for a good tone, more force than the flute, with less freedom of breathing. The larger instruments, while requiring less pressure, demand larger lung capacity and more frequent breathing and, so, more muscular exertion.

While conclusions favorable to the use of this exercise have been drawn, I hope the possible objections have been carefully pointed out. It certainly is not the aim of the writer to set all the world a playing on pipes and a tooting on trumpets, with the expectation of thereby ridding mankind of all affections of the respiratory tract. Unfortunately, the organism and its relations are too complex for such results. However, this

exercise, not forgetting its proper limitations, should not be overlooked as a simple, safe, and pleasurable method of helping in the more complete development (up to the bounds of individual heredity) of the resistive powers, and possibly as an aid in helping Nature rid herself of conditions opposed to health and life.

Pressures Necessary in Producing Vocal Sounds and in Playing Upon Wind Instruments.

(Registered in Centimeters of Mercury.)



APPENDICITIS.

TO OPERATE OR NOT TO OPERATE.

By J. J. BROWNSON, M.D.,

DUBUQUE, IOWA.

In November, 1903, I read a paper before the Austin Flint, Cedar Valley Medical Society at New Hampton, Iowa, giving my views on operation for appendicitis, as practised by me in this locality for the past fifteen years. The principles upon which I based the time for operation were as follows: There have been more deaths from appendicitis since the operative method has been in vogue than during the expectant plan, which I believe is due to interference being practised at the wrong time.

1. The operation for appendicitis ought to be done in the primary stage or before high fever period. The appendix should be removed, to guard against fulminating cases and those in which rupture occurs into the abdominal cavity.

2. In the secondary period after suppuration, drainage should be instituted, and nature left to take care of the appendix.

3. In the interval, after all symptoms of inflammation have subsided, the appendix should be removed.

The operation ought not to be done in the intermediary period when there is fever and distention of the abdomen, because the danger from operation at this period is greater than the risk of the case becoming fulminating, or the abscess bursting into the abdominal cavity.

Since that occasion I have kept a close observation upon the results of operation for this disease in Dubuque county, not only in my own, but in the practice of other physicians. I am pleased to state that while many of my confreres did not at the meeting openly coincide with my ideas as to the time for operation in this disease, yet I noticed that the principles of the article were being quite closely followed. As a result there have been but two deaths in this county from appendicitis, following operation, since the publication of that article in *American Medicine*, January, 1904; while at the same time, so far as I know, there has been no operation performed for appendicitis during the intermediary period of the disease.

It will perhaps be interesting to know some of the points brought out in the discussion of my paper before the society at that time. Much to my surprise, the trend of that discussion, which was led by two of Chicago's prominent surgeons who were present at the meeting, seemed to be directed to the treatment of appendicitis when abscess with adhesions had formed. The Chicago gentlemen denounced as most unscientific and unsurgical the proceeding which would simply open the abscess and leave the appendix. They very forcibly declared: "Go down and break up the adhesions. Open up, clean up, and remove the appendix." They probably overlooked the fact that when nature forms the abscess the portion of the appendix that is diseased sloughs away and is removed by that same process of nature that eliminates the materies morbi from any part of the system when suppuration and evacuation take place. Everyone knows that should recurrence take place in one of these cases where the abscess had been evacuated it would follow up the old scar and there would be no danger of the pus breaking into the abdomen.

A surgeon of great prominence in the East reports very successful results in what we have hitherto called cases of acute septic peritonitis, caused by perforation of the appendix or the bursting of an abscess pouring the septic contents directly into the abdominal cavity. A great many of us in the West have always regarded these cases as surely fatal. From the description given by the gentlemen in the East, the cases they call acute septic peritonitis (the symptoms being a pulse of 120 to 130, temperature 102°, with prostration and pus diffusing into the peritoneal cavity) are here in the West regarded, not as acute septic peritonitis, but rather as abscess with adhesion or incapsulation. On close examination it will be found that no case of acute septic peritonitis, caused by the direct perforation of the peritoneal cavity, will be found with a temperature of 102° or a pulse of 120; rather will they have a temperature of 105° or 106° and pulse of 140 or 160, together with a leaky skin and such extreme prostration as to make it plain that the patient is thoroughly overwhelmed with the poisonous principles and is practically moribund. These are the cases which result from the waiting plan in the abscess period and result in death, no matter what procedure is followed. It is better in these conditions to let nature take its course and not to attempt a forlorn task which injures the reputation of both the operator and the science of surgery.

The so-called "starvation treatment" is really no treatment at all. It is simply awaiting the proper period for operation, should such period come. The symptoms in these cases of appendicitis, to a certain extent, are the same as in typhoid fever, so near akin indeed as to permit us to use them for comparison. The greatest danger of death from appendicitis is from perforation: one of the greatest dangers in typhoid fever is also from perforation. The truth is that a thousand cases treated by the "starvation method" would exhibit no better results than would be shown in a like number of cases treated by the ordinary expectant plan with the administration of proper liquid nourishment, as is usual in typhoid or other fevers. The theory that starvation keeps the intestines quiet is untenable, for it is well known that the intestinal canal is never quiet unless under the influence of morphine, and the use of this drug in such cases is decried by nearly all authors. Indeed, some of the best authorities prefer the opposite treatment—catharsis; and they report fully as good results. If one will follow the conclusions reached

in my paper, published some years ago, and which conclusions I am happy to say are confirmed by clinical results and are now approved by the best authorities, he will agree that there is in the course of appendicitis a period when the treatment must be nonsurgical. Such time is the intermediary period, marked by great distention and high fever. If we desire to give the patient the benefit of the wisest, most conservative, modern philosophical treatment we must refrain from surgical interference during this stage of the disease.

Of course there is risk in the expectant treatment, as there is in the operative treatment, but to me the question to be decided is, "Is the condition of the patient and the period of the disease such that it is more dangerous to operate than it is to postpone operation?" It is now generally conceded that the risk of an operation is greater during the intermediary period than the risk of perforation, and this view is confirmed by clinical results. Hence we conclude that when the disease has reached the intermediary stage a wise and judicious expectant treatment is the safer course. Should an abscess form, it must be promptly treated by proper drainage, as previously indicated. If no abscess form, the case will go on to resolution and the patient will recover. As to the other periods of the disease, the advisability of operation and the technique are fully settled.

It will perhaps be of interest to give the comments of some of the leading men on the above propositions as stated in my paper, after it was published nearly three years ago. One of the greatest authorities on appendicitis in this country thus writes: "You have boiled down the subject to some very substantial and practical facts, and I feel that your paper would make a good guide for the general practitioner." A professor of surgery in one of the universities says: "I desire to thank you for the copy of your article on appendicitis. More than that, I want to congratulate you upon having reached conclusions that are sound and impregnable. My experience, which has been considerable, coincides directly with your own, and the facts are so indisputable and easily demonstrated that I marvel when I hear of men going directly in the face of them, as many do." Another prominent physician said: "I have just read your New Hampton paper on appendicitis. I am becoming more and more convinced that the principles advocated in said article are correct." One of the leading authorities in medicine said: "The mortality throughout the country at large, in appendicitis, is probably greater now, owing to the indiscriminate operation by men who are not experts." A leading medical editor said: "I am much pleased with your views, as they correspond exactly with mine." One of the officers of the society writes: "Notwithstanding the fact that your conclusions were not concurred in by gentlemen present whom we are bound to respect and acknowledge as more or less authoritative, yet I believe that at least in the work of private practice without expert facilities you are right beyond a reasonable doubt." A practitioner of long experience says: "I have long since become satisfied that operation for the removal of the appendix under any and all circumstances has sacrificed many lives that might have otherwise been saved."

In a paper published in *American Medicine*, August, 1904, Dr. H. Wetherhill says: "Were I or one of my very dear friends in the third to sixth day (intermediary period) of peritonitis of appendicular origin, and obliged to make a choice of some gray-beard with half a century of empiricism back of him, or that of some modern surgical enthusiast of the 'operate as soon as the diagnosis is made' sort, I would not hesitate a moment in choosing the former. However brilliant and dexterous and famous an operator might be, I would not select him if he had a penchant for operating on sight and for removing the appendix regardless of its situation and surroundings. I am far from alone in believing, on the other hand, that intermediary operations are usually attended with a general mortality, and that indeed they are sometimes directly homicidal."

The prime object in the treatment of appendicitis is to prevent the usual cause of death, viz., perforation. Of course the question would devolve itself into, "Would the danger of removing the appendix during this period be greater than the risk of the appendix perforating?" I might go on and cite opinions and instances by famous authors everywhere, but it would take up too much time. I only wish to say in conclusion that a conservative, close observation of these cases in a moderate surgical practice in this locality for fifteen years leads me to state that the intermediary period is the time when a surgeon should withhold his hand.

I repeat: "To Operate or Not to Operate?" To operate in the primary period, in the abscess period, and in the interval period. *Not* to operate in the intermediary period, when there is great distention and high fever, because the risk of perforation of the appendix is less than the risk of operation at this period.

I believe and I hope that everyone who reads these conclusions carefully and ponders over them and observes the results, not only in his own practice, but in that of others, will be convinced of their truth, so that the publication of them will, I trust, be considered at least a slight attempt to establish landmarks and guideposts in the management of appendicitis.

Regarding the two deaths above referred to, following operation, one occurred in the practice of one of my friends; it was the case of a child that was operated on in the abscess period and died some two weeks after operation. The case of death following operation in my own practice was as follows: Miss Q., age 23, had had previous attacks of appendicitis. I was called in consultation with Dr. Heles to see her on the third day of the disease. Her temperature was 100° and her pulse 90; no distention, but extreme tenderness in the McBurney region. She had vomited the day previous and on the morning I saw her. Operation was advised and accepted, and she was removed to the Mercy Hospital in the afternoon. The operation was performed at 3 P.M. On opening the abdomen, the appendix, very greatly enlarged, imbedded in a mass of adhesions, was enucleated with considerable difficulty, but finally removed without perforating. It was very much enlarged and contained pus and a concretion as large as a kidney bean. The concretion had acted as a ball valve, allowing the contents to pass from the bowel into the appendix, but preventing their return. The constant pressure had so increased the size of the appendix as to produce almost ulceration at the points of its juncture with the cecum. The operation was quickly done, without any accident, and the wound closed as usual. The patient reacted well and I left for St. Louis that evening. Dr. Heles furnished me the remaining history of the case, which was as follows: "The patient reacted well, fever dropped, pulse became normal in a day or two, and everything went along to a most speedy convalescence. The stitches were removed on the tenth day. On the evening of the fourteenth day, after entertaining her friends for an hour or two in

the evening and dismissing them with a good-night, saying that she was going home in the morning, they left. She requested the nurse to turn down the light, so that she could get some sleep, as she was going home in the morning. The nurse did as she was requested and left the room. In about five minutes the bell rang, and when the nurse entered the room Miss Q. sat up in bed and said, 'Open the window; I am smothering,' and fell dead upon her pillow."

On talking with some of her friends afterward I learned that she had had, two years previous, while attending a picnic, a fainting spell, from which she was revived with great difficulty. From the history and outcome of this case, which, of course, had nothing to do with the operation, I am inclined to think that death was caused by probable heart clot.

As stated, this is the case in which I had death following operation for appendicitis; it shows, however, that no matter how careful or accurate we may try to be, work by human hands will never attain perfection.

Spastic Constipation.—T. W. Stumm, in his paper on this subject, declares that treatment is the most important thing in these cases. The physician must remember that he has to deal with an irritative condition in the large intestine, and that the ordinary means resorted to in relieving atonic constipation will only aggravate it and make it worse. The patients usually try all the cathartics known to them, and find that they only make the condition worse. The diet must be selected with great care. Patients suffering with spastic constipation should be given foods that are bland and non-irritating. Such a diet, rich in cellulose, as is ordered in atonic constipation, will only aggravate spastic constipation, by increasing the irritation in the intestine. Pickles, cabbage, turnips, cucumbers, pork, pickled meats, goose, strong coffee, and tea should be avoided. Fruit may be allowed, but would much better be cooked than raw. Food that will excite peristalsis through a chemical action rather than a mechanical one should be selected. In contradistinction to atonic constipation, the patients do much better with only moderate exercise. Sometimes rest in bed for two or three weeks will do much good. Warm baths and hot applications to the abdomen are beneficial in causing a relaxation of the spasm. The baths should be taken just before going to bed, and heat in some form, applied while in bed, is helpful. During the day the abdomen should be well protected with woolen cloths. Medicinal treatment in such cases is not satisfactory. Cathartics in all forms should be avoided. Belladonna or opium acts very well in relieving the spasm, but the best therapeutic results are obtained through the injection of olive oil, or what is equally as good, cottonseed oil. This is used at first every night, later every second night, and then once or twice a week, as it is needed. After a time it may be entirely discontinued. The action of the oil is probably threefold; it lubricates the mucosa of the intestine; it softens the intestinal contents; it further aids chemically in splitting fatty acids. The last action is probably the one that causes an increased peristalsis through chemical excitability. The writer adds that, in order to secure results, the oil must be properly injected. It should be given before going to bed, and retained until morning. The ordinary individual will retain a pint. The patient should lie on the right side, the left limb extended, the right flexed at the knee and placed in front and over the extended left one. The oil, at a temperature of 100° F., is allowed to run slowly into the intestine through a moderate-sized rectal tube passed seven or eight inches into the rectum. The patient should then remain perfectly quiet. If the hyperacidity is annoying, it may be necessary to order a little magnesia for a time, but an excess of fat in the diet will usually overcome any acidity. Small doses of Carlsbad salts, but not enough to act as a laxative, may be used instead of the magnesia or the fatty diet, if the physician does not care to employ these. It is sometimes necessary to employ bromides if marked nervous symptoms are present. Such means as are outlined here usually secure good and lasting results. Electricity, massage, violent exercise, cold baths, and other measures employed in atonic constipation should not be used in the treatment of spastic constipation.—*The St. Paul Medical Journal*

Ante- and Post-Operative Treatment of Cancer of the Breast.—George C. Johnston says that the changes taking place in carcinomatous tissue when exposed to therapeutic doses of Roentgen rays, consist of a breaking down of the islands of diseased cells, beginning and most pronounced in the rapidly-growing periphery. A peculiar endarteritis of an obliterating type attacks the blood-vessels, which are surrounded by masses of small cells. This degeneration is apparent in even the deepest part of the tumor. A dosage can be formulated and administered strong enough to destroy the pathological tissue, but sparing the normal. In addition to the change in the tumors and the blood-vessels, a peculiar action on the lymphatics, both vessels and glands, is noted. The former are, as it were, sclerosed. The glands are small, hard, fibroid masses. If there were no other factor to be considered, radiation might be regarded as an agent fulfilling every indication to be desired in the treatment of this disease. Yet the fact has to be accepted that the use of the ray alone in the treatment of carcinoma is jusified in but few cases. As of old, the mainstay is careful complete surgical extirpation in operable cases. On the other hand, operation alone cannot boast of a remarkable percentage of cures. The writer describes a course of radiation which he believes will accomplish the desired prophylactic result in the majority of cases. He is convinced that cases of extensive carcinoma may be taken in charge, rayed, operated upon, and by a continued post-operative treatment freed from carcinoma. Successful work demands the intelligent cooperation of the surgeon and the radiologist. Much can be accomplished when these two work together with a full knowledge of the limitations of their art. The *x*-ray must not break down more tissue than the patient can successfully eliminate, and the knife must not remove more tissue than is absolutely necessary. The writer states that a large percentage of successful results need not be expected, but he believes that failure should stimulate repeated endeavors. He holds that the cure of one ordinarily hopeless case is a greater victory than a long series of successful results in ordinary, primary cases.—*Archives of Physiological Therapy*

Fat Indigestion from a Mother's Milk.—W. P. Northrup gives the history of this case in which a mother, anxious to nurse her child, fell into misfortune through trying to follow the conflicting advice of several physicians. If any one efficient practitioner had had the sole responsibility of the case, all mishaps would have been prevented. An attack of tonsillitis on the part of the mother apparently disturbed the baby's digestion somewhat. The second attack with its consequent anemia wholly upset it. An excess of fat was found in the mother's milk, apparently produced by forced feeding, including a quart of milk daily, lack of exercise, indoor living, and two attacks of tonsillitis. This excess of fat brought about in the infant ileocolitis with the symptoms of diarrhea (no vomiting), with frothy, brownish to olive-green, offensive passages, containing an excessive amount of mucus in tenacious masses, colic, sleeplessness, and loss of weight. The fat in the milk was lowered by diet and driving in the open air, from 8.98 per cent. to 4.90 per cent. The infant became susceptible to the presence of the least trace of milk in her food and could not digest it for a time. Castor oil and barley water were given and irrigations were resorted to. The child recovered. The writer states that in another case of this kind he would take the baby from the breast at once.—*Archives of Pediatrics.*

New York, September 6, 1906.

EXPERIMENTAL WORK IN GASTRIC PHYSIOLOGY.

A VERY considerable portion of the *Festschrift** recently published under the direction of Professor Orth by the workers in the Pathological Institute of the University of Berlin in commemoration of the opening of the new buildings of that department is devoted to a series of studies on gastric physiology. The work of the institute is carried out in three departments, devoted respectively to pathological anatomy and histology, including bacteriology, to biological chemistry, and to experimental biology. The latter of these, of which Adolf Bickel is the head, has been equipped with unusual facilities for operative work on animals, and the technically rather difficult surgical procedures required in studies of this sort could therefore be prosecuted under the most favorable circumstances. A portion of the observations were made on dogs which had been subjected to the Pavlov operations. In one of these, as is well known, a gastrostomy is done and later the esophagus is divided in the neck and the end communicating with the stomach is closed while that leading from the mouth is sutured to the skin. Such dogs must be fed through the gastric fistula, as food taken into the mouth passes out again through the opening in the neck. The other operation consists in the formation of a gastric diverticulum, or lesser stomach, which is completely shut off from the remainder of the organ and is provided with a fistula leading to the surface. Food swallowed enters the main cavity of the stomach, and the secretory activities of this portion of the organ are reproduced in the lesser stomach, from which gastric juice may be obtained for analysis entirely uncontaminated. The reflex secretion obtained from animals of the former type represents the activity of the entire gastric mucosa, but is the result of only a fraction of the normal physiological stimuli, since the food never comes in contact with either the gastric or intestinal walls. Animals of the second group produce juice formed in response to normal stimuli, but not typical of the entire stomach, since it is manufactured only by a portion of the fundus. The results to be described were obtained from the study of such experiment dogs, and also comprise what, according to Bickel, are the first observations made on an adult human being presenting conditions similar to those occurring in these laboratory animals. This person was a girl of twenty-three years who eight years previously had acquired an impermeable stricture of the esophagus in consequence of poisoning by lye. After having been nourished for some years through a gastric fistula, the esophagus was divided in the neck, the lower end buried, and the upper end brought to the skin surface. By connecting this opening with that in the stomach by a rubber tube the patient, who had almost forgotten how to chew and swallow, was enabled to take her food by mouth. On removing the rubber tube the same conditions existed as in the experiment dogs. Roeder and Sommerfeld have reported observations made in a similar case, but this patient was a child of twelve years.

Many of the investigations made by Bickel and his collaborators relate to freezing-point determinations, electrical conductivity, and ultramicroscopic observations, and the results obtained, while of value from the laboratory standpoint, are not, yet at least, directly helpful to the clinician. Others, however, bear directly on practical matters and should prove of much interest to practitioners. For example, it appears that, although the secretion of the specific substances of the gastric juice is an intermittent process, mucus is being constantly formed, and in consequence the mucosa of the resting stomach is alkaline to litmus. Silver nitrate and other caustics evoke an active secretion of mucus, but especially is this the case with the electrical current, which causes the production of mucus alone without any of the components of the true gastric juice. No matter how applied, percutaneously or endogastrically, whether strong or weak, galvanic or faradic, the electric current, according to these observers, is valueless as a stimulus to the digestive functions of the stomach, and the gastric electrotherapeutists will have to revise their doctrines. Furthermore, an abnormal secretion of mucus can be produced experimentally only by local stimulation of the mucosa, and only those regions directly irritated respond by forming mucus. That the secretion of gastric juice can be encouraged to a remarkable degree by stimulating the senses of taste or smell is well known, but it was found that it made no difference in the effect on the gastric mucosa whether the sensory impression were an agreeable one or not. For example, both quinine and asafetida were very repugnant to the young woman with the gastric fistula, yet their administration influenced the secretion favorably. The inhibiting effect on secretion of strong emotions could be strikingly demonstrated in the case of one of the experiment dogs that always flew into a violent rage when a cat was placed near his cage. Whenever this was done the flow of secretion was abruptly checked. Another observation of practical importance was that the same individual on different occasions responded differently to the stimulus of the same amounts of the same foods, on some days more juice being formed than on others. The more juice is secreted, the higher will appear to be the acidity of the stomach contents, which does not depend so much on the percentage strength in acid of the juice as on the amount of juice secreted. The unreliability of the results obtained from the analysis of a single test meal is evident, as the same stomach may on different days show great fluctuations in secretory

* Arbeiten aus dem Pathologischen Institut zu Berlin, Herausgegeben von Johannes Orth. August Hirschwald, Berlin, 1906.

activity. On the other hand, although the quantitative variations may be great, the gastric mucosa appears to be provided with a regulating apparatus which is very efficient in controlling the composition of the juice, for this is subject to astonishingly slight changes. A highly interesting series of studies is devoted to the effects of the different foods, condiments, etc., on the gastric secretion, and remarkable variations in the effect of different substances are recorded. Fat and solutions of sugar and starch are no more stimulating than water, and even egg albumin has little value in this respect, while tea is directly inhibitory.

It would lead too far afield, however, to endeavor to follow this group of workers through the entire range of their explorations in gastric physiology. The results obtained bear on many aspects of the disorders of the stomach and their treatment, but especially do they contribute to an understanding of the intimate relationship existing between the nervous system and the digestive function. Since it is the nervous dyspeptics who contribute the lion's share of the revenues of the stomach specialists, we opine that this series of experimental observations will be found of unusual interest and value to those concerned with this branch of medicine.

THE SANITARY ASPECT OF THE RE-OCCUPATION OF CUBA.

When, nine years ago, the situation in Cuba was seen to be approaching an acute stage, and it became apparent that the only relief would be in American occupation of the island, the Medical Record predicted that one of the greatest benefits to follow such occupation would be the sanitation of Havana and the freeing of our southern ports from the constant menace of yellow fever. The result even surpassed our anticipation, for the confirmation of Finlay's mosquito theory by the convincing experiments of Reed, Lazear, Agramonte, and Carroll, and its practical application by Gorgas, effected a sanitary revolution unequaled in the world's history. Havana, the center and the distributing point of yellow fever, and a city scourged by smallpox as well, became in less than a year, with all its natural disadvantages and still unsewered, one of the most healthful cities of the world.

For some time after the evacuation of Cuba by the American Army, Havana remained free from yellow fever, but for over a year disquieting reports have come from the island that the disease was regaining a foothold in the larger cities, and it would seem that the political disturbances necessitating a reoccupation of the country by the United States forces have come opportunely from a sanitary point of view. It is reported that on October 1 there were five cases of yellow fever in Havana and several suspected cases in Cienfuegos and other places in Santa Clara Province. The commercial interests in the island have welcomed the resumption of American control, but no less warm is the welcome of the hotel keepers, the transportation companies, and others interested in tourist travel, who have been affected injuriously by the reimposition of quarantine against the island. It is said that they are preparing to petition Gov. Taft that the United States, whether the present American control be temporary or otherwise, retain permanent control of the sanitary affairs of Cuba. These interests contend that inasmuch as the Cuban government has failed to carry out the requirements of the Platt amendment with respect to sanitation, the United States is justified in permanently taking over the sanitary supervision of the island.

This is not to be construed as a reflection upon the present chief of the sanitary department of the island, for those who know what obstacles he has had to contend against in the administration of his department have only admiration for what he has achieved. He has been hampered in his work at every turn by lack of funds and by want of power to enforce his decrees, and the wonder is that he has kept the city and the island as free from disease as they are even to-day. But a health officer, in his war against disease, must have unquestioned and absolute power, and this, in a young country like Cuba, with its insanitary traditions of centuries, can be enforced only by military authority; the civil hand is as yet too weak. It will not be necessary to supersede Dr. Finlay, for he has proved his efficiency; but he should have the power of the United States behind him, and he and his successors should be, for many years to come—long after the civil administration of the island has been again delivered into the hands of the Cubans—under the control of the Army or of the Public Health and Marine Hospital Service, and supported in their task by the authority of the United States. Only in this way can Havana be kept, as it was made by Col. Gorgas, an inoffensive neighbor of our Gulf and South Atlantic cities.

THE SALOON AS A DISSEMINATOR OF DISEASE.

The saloon in every civilized country is regarded by a certain section of the inhabitants as a formidable menace to health. While this is true to some extent, and while drinking to excess wreaks more harm physically and mentally than any other cause, yet it has not as yet been absolutely proved that the consumption of alcoholic beverages, taken with discretion and at the proper time, does harm. On the alcohol question the opinions of medical and scientific men are strangely divergent. Some leaders of the medical world, as Sir Victor Horsley and Professor Sims Woodhead in England, hold alcohol in abhorrence and state that as a drug it is useless and as a beverage it is pernicious. Other equally distinguished leaders of science, as Professor Atwater, Professor Chittenden, and most of the German scientists who have made investigations into the matter, state that alcohol has its uses and forbear to stigmatize it as utterly destructive to body and mind. A large proportion of English-speaking medical men reserve their decision on the subject until more has been determined concerning the action of alcohol than is at present known. This, in the face of the results of numerous experiments which have taken place during the past few years, is probably the wisest course to pursue. At the same time it is satisfactory to note that drinking of alcoholic stimulants has never been so prevalent here as in Europe, and that the people of America on the whole are a temperate race.

The saloon, however, is in many instances the means of originating and disseminating disease, irre-

spective of drinking. This is especially the case when such establishments are not kept in a sanitary condition. Two special articles dealing with this matter in Great Britain, which appeared in the *Lancet* a number of months ago, contain the results of a very careful investigation of the subject. Of course, it is not easy to compare the public houses of London and the saloons of New York, viewed from a hygienic standpoint. Many, if not most, of the London establishments in the poorer quarters of that city cannot by the widest stretch of the imagination be termed sanitary. In fact, as the writer in the *Lancet* states, "The question of sanitation is almost wholly disregarded in the management of public houses." The so-called private bars of the British public house are unknown in this country. These bars are merely narrow boarded compartments opening onto a common counter and are presumably provided for the convenience of women or of those who do not wish to drink in a public house in the full sight of their fellow men. Such compartments are naturally often overcrowded, and one who uses them is compelled to rub shoulders with all sorts and conditions of men, regardless of their sanitary state.

It has been proved more or less conclusively that pulmonary tuberculosis is spread by the agency of public houses in Great Britain, and this is probably also the case to a lesser extent in regard to saloons of America. Although the saloons here are far cleaner and better ventilated than are those of Great Britain, there are many in which diseased and unwashed loafers spend a great part of their time. There are many other affections which may also be easily spread by means of the saloons. Among these are diphtheria and other infectious diseases, syphilis, and almost all forms of skin diseases. Over and above the fact that American saloons, as a rule, are far cleaner and more hygienic than the British public houses, there is one lamentable feature of drinking in Great Britain which is absent here. The habit of drinking among women in public bars is referred to. Drinking by women is practised everywhere, but in no other part of the civilized world can it be witnessed to such an extent as in Great Britain. What are known in England as respectable women are accustomed to foregather in the public house for the sole purpose of drinking and gossiping. No particular loss of self-respect attaches to the woman who does this, and consequently the custom shows no signs of declining.

We may, on the whole, congratulate ourselves that, although in many matters hygienic we are not quite in the front, at least our saloons will compare favorably with those of the other great English-speaking people.

The Ethics of Manufacturing.

Much has been written of late in the medical journals of this country on the ethics of proprietary remedies, both those prepared solely for physicians' use and those advertised to the general public. With the exception of one or two journals in which the denunciation of almost every drug, simple or compound, not listed in the Pharmacopœia, and even of some long since admitted to this compendium, has reached hysterical proportions, this discussion has been reasonable and sound, and the agreement has been reached that physicians are within their rights in seeking to know the ingredients and their relative proportions contained in all compound remedies offered as aids in the treatment of disease. The details of the methods employed in the compounding of these preparations are not essential, since few physicians would understand them if they were published, and they may properly be regarded as trade secrets the revealing of which would only result in depriving the manufacturers of the legitimate reward of their labor. As yet, we regret to say, the agitation has not had the desired effect, since inquiry among pharmacists shows that physicians continue to prescribe the secret remedies in spite of the anathemas of the violent and the arguments of the reasonable. The reason for this is probably that the prescribers have found the remedies effectual and so continue to use them empirically in cases in which they believe they are indicated. It will take time to bring the mass of the profession, as well as the manufacturers, to view this matter in the proper light, and the more soberly the subject is discussed and the less vituperation is used in place of argument, the sooner the looked-for reform will be effected. The *American Journal of Clinical Medicine* has gone a step further than most of its contemporaries in applying the test of ethics to the manufacturers as well as to their individual products. It calls attention to the well-known fact that some drug houses which offer perfectly ethical preparations to the profession also manufacture many of the quack medicines advertised to the public, not selling them themselves, but supplying them to the conscienceless proprietors who cater to the public craving for "dope." It asks whether all the preparations of such manufacturers should not be placed under the ban of professional disapproval. This is a large question, and apparently sound arguments may be urged on both sides. Our own opinion is that it is nobody's business, but his own, what a drug manufacturer may do in addition to making "ethical" preparations for physicians' use, so long as he does not offend against the law of the land. But if we must insist upon a certificate of church membership from our shoemakers and drug manufacturers, since the Council on Pharmacy of the American Medical Association has undertaken to determine the ethics of proprietary remedies in general, the question of the moral character of the manufacturers of these preparations would seem to be one equally within the scope of its investigation.

The Cure of Strabismus.

The unsuccess which in former times attended tenotomy for the cure of strabismus constituted one of the opprobria of ophthalmic surgery. Babies a few months old were operated upon, the muscle of one eye only, the one which the surgeon assumed to be the offender, being divided, and in a year or two the squint was found to be as bad as before; another operation was performed, and perhaps another, and the defect remained. The reason for this failure to relieve was, as Dr. D. B. St. John Roosa has pointed out in various papers published in the Medical Record and elsewhere, that the measures employed were directed to the effect only, the cause of the condition being unrecognized and untreated. He returns to the subject in a clinical lecture in the *Post-Graduate* for July, 1906, and insists that the operation, which he performed before the class, is to be regarded as only one of the steps in the curing of squint. Functional strabismus, he says, is invari-

ably caused by an error of refraction, and unless this error is corrected by glasses the efforts of the surgeon are doomed to failure. Indeed, the attempt should always be made to relieve the condition by glasses first, and resort should be had to operation only when these have been found to be insufficient. For this reason operation upon infants is inadvisable, since at an early age, before they begin to distinguish such small objects as letters and figures, they cannot usually wear glasses with profit. The operation which Dr. Roosa prefers is that of Panas of stretching and division of the muscle, both eyes being operated upon at one sitting. The operation has not the element of danger associated with advancement, and it is much less liable to be followed by overcorrection resulting in divergent squint. The operation of advancement is necessary in certain cases, but it should be reserved for those cases and not employed as a routine measure. In fitting glasses after the operation Dr. Roosa's practice is to correct only the astigmatism, and not the hypermetropia in the eyes of young subjects.

News of the Week.

Dr. L. Duncan Bulkley will, during the coming winter, deliver his eighth course of clinical lectures on diseases of the skin in the out-patient hall of the New York Skin and Cancer Hospital on Wednesday afternoons at 4:15 o'clock. The first lecture will be delivered on Wednesday, November 7. These lectures, which have always attracted large audiences, are free to medical men.

Reappointment of Surgeon-General O'Reilly.—The President has reappointed Dr. Robert M. O'Reilly, Surgeon-General, U. S. A., to serve a second term of four years.

Dr. L. G. Hanley, Surgeon of the Sisters of Charity Hospital, Buffalo, N. Y., was, on September 26, 1906, given the degree of LL.D. at Niagara University, Niagara Falls, N. Y.

Dr. H. S. Frenkel of Heiden, Switzerland, well known for his compensatory method of treating locomotor ataxia, will visit New York early in November for the purpose of demonstrating the principles involved in his system, and of pointing out in what type of cases it is likely to be successful. It is announced that he will read papers before several of the medical societies.

Child Labor Laws.—The amendment to the labor law concerning the employment of children, which was enacted by the last legislature, went into effect on the first of October. The amendment makes it unlawful to employ children under sixteen years of age in any factory in this State before 6 A. M. or after 11 P. M. The employment of children under the age of sixteen is prohibited in New York City after 7 in the evening in any mercantile establishment, business office, telegraph office, restaurant, hotel, apartment house, or in the distribution or transmission of merchandise or messages. No child under sixteen years of age, and no female, shall be permitted to work in any mine or quarry.

Inspection of Bakeries.—The law providing for the inspection of bakeries and confectioneries in this State went into effect on October 1. This law provides that "if, on inspection, the Commissioner of Labor find any bakery or confectionery to be so unclean, ill-drained, or ill-ventilated as to be unsanitary, he may, after not less than forty-eight hours' notice in writing, to be served by affixing the notice on the inside of the main entrance door of said bakery, order the person found in charge thereof immediately to cease operating it until it be properly cleaned, drained, or ventilated. If such bakery or confectionery be thereupon continued in operation or be thereafter operated before it be properly cleaned, drained, or ventilated, the Commissioner of Labor may, after first making and filing in the public records of his office a written order stating the reasons therefor, at once and without further notice fasten up and seal the oven or other cooking apparatus of said bakery or confectionery, and affix to all materials, receptacles, tools, and instruments found therein labels or conspicuous signs bearing the word 'unclean.' No one but the Commissioner of Labor shall remove any such seal, label, or sign, and he may refuse to remove it until such bakery or confectionery be properly cleaned, drained, or ventilated."

Arrests for Obstructing Ambulance.—Two negroes were arrested and fined last week for obstructing the progress of a Roosevelt Hospital ambulance by driving in front of it and refusing to heed the driver's signals.

Salaried Admitting Physicians at Bellevue Hospital.—The State Civil Service Commission has approved of the increase to the sum of one thousand dollars a year of the salaries of the four admitting physicians at Bellevue Hospital, whom it is now proposed to appoint. These physicians are to replace the members of the house staff who have heretofore attended to this work as a part of their duties. The eligibility for appointment is limited to persons who have served for at least two years in Bellevue Hospital. They are to serve for six hours a day, under such rules and regulations as may be prescribed by the Board of Trustees. Applications may be sent to Mr. James K. Paulding, Secretary of the Board of Trustees, at the hospital.

Conference of New York Sanitary Officers.—The Sixth Annual Conference of Sanitary Officers of the State of New York will be held at Syracuse, October 24 to 26, 1906. The program includes discussions on tuberculosis, meat inspection, water supplies, sewage disposal, disinfection, etc.

Meat Scandal in Vermont.—The Attorney-General of Vermont, in a report to the Governor of the State, charges gross negligence on the part of the Cattle Commission of Vermont. It is alleged that the Commission did not strictly follow the law, which requires that the carcasses of condemned animals shall be buried, and in several instances it has appeared that the Commission took the condemned animals to a slaughterhouse and had them slaughtered there, and disposed of the carcasses for fertilizing purposes. It is further stated that 200 condemned cows were sold by a member of the Commission to a drover, who took them into Massachusetts, where all but twenty of the animals were slaughtered and sold for food.

Registration of the Blind.—The Commission for the Registration of the Blind of this State, consisting of Dr. F. Parke Lewis of Buffalo, W. J. McClusky of Syracuse, and E. Morford of Brooklyn, met on September 29 and organized by electing Dr. Lewis president, and O. H. Burritt, superintendent of the State School for the Blind, at Batavia, secretary. The commission

announced that it would welcome suggestions regarding its efforts to improve the condition of the blind.

Public First Aid Cabinets.—A number of cabinets, containing dressing materials and other appliances likely to be of use in emergencies, have been placed in the streets of Leicester, England. The cabinets are kept locked, but can readily be opened by breaking a glass door, in the same way as fire alarm boxes.

New Sea View Hospital.—Bids will be opened on October 15 by the Charities Department for the group of buildings to be erected by the city at Castleton, S. I., which, when completed, will be known as the Sea View Hospital. The buildings will comprise eight four-story structures to be used as wards, and in the center of this group will be a chapel. Reinforced concrete will be used extensively in the construction. The buildings will cost about $1,000,000.

Straus Milk Stations Closed.—On September 24 the fourteenth season of the Nathan Straus milk depots ended, and the booths for the distribution of pasteurized milk in the public parks and on the recreation piers were closed. The quantity of pasteurized milk distributed exceeded that of any other year. The total number of bottles dispensed was 3,142,252, and the number of glasses of milk drunk on the piers and from the booths in the parks was 1,078,405. Contracts have been signed by Mr. Straus for the erection of a building at 348 and 350 East Thirty-second street, to be devoted exclusively to the pasteurization and modification of milk for the tenement babies.

Railway Casualties.—According to a statement issued by the Interstate Commerce Commission, in the course of twelve months an average of 26 persons were killed and 238 injured a day on railroads in the United States. The total number killed during the year was 9,703, while the injured numbered 86,008.

Honorary Degrees.—Among those receiving the honorary degree of LL.D. at the quatercentenary celebrations of the University of Aberdeen, held two weeks ago, were Dr. Howard A. Kelly of Baltimore, Dr. A. B. Macallum of Toronto, and Dr. J. William White of Philadelphia.

Honorary Degrees Conferred at the Harvard Dedication.—The following honorary degrees were conferred at the academic session held on September 26 in connection with the dedication of the new buildings of the Harvard Medical School: Charles Allerton Coolidge, architect, honorary doctor of arts; Dr. Simon Flexner, honorary doctor of science; Dr. John Collins Warren, doctor of laws; Dr. Henry Pickering Bowditch, doctor of laws; Dr. Abraham Jacobi, doctor of laws; Dr. José Eames, professor of pathology and chief of the clinical staff in the Medical School of Mexico, doctor of laws; Dr. Franz Keibel, professor of anatomy in the University of Freiburg, doctor of laws; Dr. Charles Scott Sherrington, professor at the University of London, doctor of laws; Dr. Francis John Shepherd, professor of anatomy in McGill University, doctor of laws; Sir Thomas Barlow, professor of clinical medicine in the University College Hospital, doctor of laws.

Beer Drinking in France.—The statisticians announce that the consumption of beer in France has increased more than 40 per cent. during the past five years, while the amount of absinthe used has shown a corresponding decline.

Cocaine in India.—The cocaine habit is said to have become so serious a menace to the prosperity of India that the government has formulated the most drastic regulations to check the increase of the vice. Even the mere possession of the drug by the laity is a punishable offense.

The Incomes of British Medical Men.—According to a recently published estimate, the incomes of English physicians have fallen off 25 per cent. during the past six years. Among the causes assigned for this decrease are the diminishing morbidity from epidemic influenza, which was very prevalent in 1900, the greater freedom from other infectious diseases, and the diminution in sickness during the winter months attributable to the mildness of recent winters.

An Epidemic of Ptomain Poisoning.—It is reported from Kattowitz, in Prussian Silesia, that thirty persons in a neighboring village have become mentally deranged as a consequence of the consumption of spoiled meat.

A League of Medical Socialists.—The newspapers have announced that a number of East Side physicians holding socialistic views are forming a league having for its object the nomination for public offices of socialist candidates.

The Tuberculosis Campaign in Berlin.—The report of the Berlin Tuberculosis Dispensary, established two years ago, has been recently issued and shows very encouraging results. Six physicians and eleven nurses attended the office ten times weekly; 15,661 persons were examined medically, and, in addition, 18,644 visits were made to dwellings, 365 beds were granted, 2,765 persons were helped with their rent and in other ways, for purposes of observation 804 persons were placed in hospitals, 622 children were sent to children's hospitals, 1,000 more to homes in the woods or other suitable places, and 8,200 dwellings were rendered sanitary. The bureau altogether spent something like 500,000 marks in its work of charity.

Registration at Columbia.—The elevation of the standards for admission to the College of Physicians and Surgeons has been followed by the expected improvement in the general character of the freshman class. For the first ten days of registration the number of students was 331, as against 405 last year. Owing to the same reason, a falling off has been reported in the attendance at the College of Pharmacy, which had dropped from 255 to 178. The total number of students registered at Columbia during the first ten days was 3,142, which is 74 less than the figure for the corresponding date last year.

American Society of Sanitary and Moral Prophylaxis.—At the regular meeting of this society, to be held at the Academy of Medicine on Thursday evening, October 11, at 8:30 P.M., the subject for discussion will be, "Venereal Infection in Children." Papers will be read and discussed by Drs. Charles H. May, J. Riddle Goffe, Virgil P. Gibney, Ludwig Weiss, W. Travis Gibb, L. Emmet Holt, William M. Polk, William P. Northrup, and others.

North Berkshire Medical Society.—The following were elected as officers at the annual meeting of this society held last week in North Adams, Mass.: *President*, Dr. A. K. Boom of Adams; *Vice-President*, Dr. G. F. Simpson; *Secretary and Treasurer*, Dr. L. A. Jones.

Mississippi Valley Homeopathic Medical Society.—At the meeting of this society held at Davenport, Ia., on September 20, the following officers were elected: *President,* Dr. W. F. Spencer of Geneseo; *Vice-President,* Dr. E. J. Ward of Rock Island; *Secretary and Treasurer,* Dr. W. F. Hunt of Davenport. The next meeting will be held in Rock Island.

Obituary Notes.—Dr. HARVEY LINK of Millard, Neb., died on September 11 at the age of eighty-two years. Dr. Link came to Nebraska in 1856, and had practised in Millard ever since. In 1867 he was a representative to the Territorial legislature, and in 1883 he was elected president of the newly organized Douglas County Medical Society.

Dr. A. H. ONG of Martin's Ferry, W. Va., died on September 22 as the result of heart failure. He had been in practice in and about Martin's Ferry for many years.

Dr. DANIEL M. SKINNER of Belleville, N. J., died on September 26 of paralysis, at the age of seventy-one years. He served in the Civil War as assistant surgeon on Admiral Farragut's flagship, and had practised in Belleville for about forty years.

Dr. LEONARD D. WHITE of Uxbridge, Mass., died on September 19 of heart disease at the age of forty-seven years. He was graduated from Harvard Medical School in the class of 1881, and began the practice of medicine in Uxbridge shortly afterwards. He had served for several years as assistant medical examiner.

Dr. W. B. FORSTER of Hope, Ark., died on September 15 at Texarkana at the age of eighty-four years. Dr. Forster was born in Alabama, and had practised in Hope for the past twenty years.

Dr. G. W. WILSON of Epperson Springs, Tenn., died of appendicitis on September 15 at Nashville at the age of forty-three years. He was born in Allen County, Kentucky, but had practised for many years in the vicinity of Epperson Springs.

Dr. Z. G. VAN ZANDT of Montrose, Ill., died on September 21 of paralysis at the age of sixty-four years. He was a pioneer physician, and had practised for many years in southern Illinois.

Dr. JOHN C. BEEKMAN of this city died at Atlantic City on September 28 at the age of forty-eight years. He had practised in Harlem over twenty years, and was on the staff of the Harlem Hospital. He was graduated from the New York University Medical School in 1882.

Dr. ANDREW FINE of Oakland, Cal., died on September 20 at the age of sixty-four years. He was graduated from the California Medical College, and after practising for some years in Watsonville settled in Oakland in 1879. For twenty-four years he was a member of the State Board of Pension Examiners, and had held numerous other official positions.

Dr. W. J. DAWSON of Los Angeles, Cal., died on September 19 at the age of fifty-eight years. Dr. Dawson had practised for twnety-three years in Los Angeles, where he was known as the "blind physician," as he had been sightless for many years.

Dr. GEORGE ATHERTON SPALDING died suddenly on October 2 at his home, in this city, of heart disease. He was born in 1849 and was graduated in 1872 from Andover College. He studied medicine at the College of Physicians and Surgeons, New York, obtaining his diploma in 1872. For a time he was an assistant to Dr. John Dalton, the Professor of Physiology in that institution. For two years he was resident physician in St. Luke's Hospital, and for the last ten years he had been an attending physician at the hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE COMING SESSION—AN EMERGENCY FUND—COUNTY COUNCIL'S SANITARY PROJECTS—"EXPERT PATHOLOGIST" ON GOAT'S MILK—SIR J. CRICHTON-BROWNE ON BIRTH-RATES AND INFANT MORTALITY, ETC.—OBITUARY.

LONDON, September 14, 1906.

THE coming event which is just now casting its shadow before a good many of us is the approaching opening of the Winter Session. The first of October is looked forward to with special interest by the teachers, with even anxiety by some, while students, old and new, are just as naturally forecasting its probabilities. The usual celebrations are duly arranged, and programs are being freely circulated. The old introductory lecture still maintains a place, but other forms of inauguration continue to encroach upon it. The teachers one meets are mostly absorbed in the consideration of the probable number of new entries. Those who are to lecture are moderately reticent as to the subjects they intend to discuss. One has heard so many discourses of the sort that it is easy to sympathize with those who have found it difficult to make up their minds.

The University of London has made so much progress with the arrangements consequent on its reorganization that the medical schools are able to include full directions in their prospectuses to students who desire to attain its degree in medicine.

The quatercentenary of Aberdeen University is looked forward to as an event of unusual interest. The King will open the new college buildings on the 27th, and Lord Strathcona will give a grand banquet to 2,400 guests in a temporary building erected for the purpose.

The British Medical Association has now organized the contemplated "emergency fund" to be created by voluntary subscriptions, to assist members of the profession in various parts of the country in defending their legitimate interests when threatened by organized bodies. It is intended to apply the fund by way of grants to practitioners, or to divisions or branches of the Association, to meet expenditures in local disputes or otherwise. There may, perhaps, be room for good work in this direction, but it seems doubtful whether the appeal for voluntary contributions will be very successful, seeing that the entire management of the fund is proposed to be kept in the hands of the medico-political committee of the Association, the record of which is not such as to inspire confidence in its discretion or its financial ability.

The London County Council is determined to obtain further powers in reference to sanitary questions, and will apply to Parliament next session for authority to deal effectually with milk inspection and supply, the sanitation of fried-fish shops and marine stores, the water supply, storage and cooking conveniences of tenement houses, the employment of another class of inspectors, and other matters, including the right to compel laundries to supply lists of their customers and to enforce cleansing on verminous persons. The Council is ever endeavoring to extend its power, and already ominous notes of objection to tyranny may be heard in various directions.

An inquest was held on Monday by Mr. Troutbeck on a laborer of twenty-one, who had been taken ill after a dose of "hygeia salts." Three other people had suffered from sickness after a dose. But there was a question as to whether some beef had not set up ptomaine poisoning There was contradictory evidence as to eating this beef. The deceased, his mother said, would not have any, and she took none herself, though she, too, had been ill. Dr. Freberger was, of course, called, and he gave the opinion that the cause of death was ptomaine poisoning from the beef, which was probably decomposed. This expert pathologist of Coroner Troutbeck recently said at an inquest on an infant that "goat's milk was worse than skim milk," and the death of the child was due to malnutrition from having been fed on it! How much more nonsense is to be palmed on juries by this "expert"?

Yesterday the annual Congress of the Sanitary Inspectors' Association was opened at Blackpool, and Sir J. Crichton-Browne delivered his presidential address. As on some other occasions, the subjects discussed by the president, though interesting from a medical point of view, were scarcely such as one would expect to occupy inspectors. He began with a reference to the diminished birth-rate, partly due, he seemed to say, to a deliberate restraint of fertility among the élite of the nation. Bearing in mind that 25 per cent. of the married population produced 50 per cent. of the next generation, and that mental and moral traits and many morbid traits were not less hereditary than corporeal ap-

pearances, it was impossible for him to exaggerate the importance of the problems raised by the statistics adduced. If, he continued, we are recruiting the population from the mentally and physically feebler stocks at a greater rate than from the more capable and healthful, the gradual deterioration of the race is inevitable. Weeds will accumulate and good grain grow scarce. It is race failure or race suicide that confronts us; if race failure is being manifested more rapidly in the superior than in the inferior societies of the race—that is to say, if the reduction in the size of families has begun at the wrong end of the social scale, then national decadence and disaster may be anticipated. The racial struggle for existence is not over—Greece and Rome are not to be forgotten. The strategy of the struggle and the weapons employed are constantly changing, but universal disarmament would only mask the conflict and perhaps hasten the catastrophe in the case of some of the more tame and less resistant, and a declining birth-rate among the best breeds means diminished racial resistance. The waste of infantile life in England and Wales is still enormous, as proved by the latest statistics. In 1904 the mortality under one year was equal to 145 per 1,000 births; but the diseases to which this sacrifice was principally due were not beyond sanitary control, and this seems to be adequate reason for impressing the sanitary inspectors with such facts. History, said the president, proves that a dwindling birth-rate is a symptom of national decrepitude, and a high infantile mortality is a prodigal waste of the national resources. Sir James next considered the prevalent diseases of the day. Neurasthenia, he said, a word unknown to Webster, is daily on the medical man's lips. To counteract the depression alcohol is indulged in, and though in amounts short of what can be called intemperance, still the amount is ultimately injurious. Overworked men and women would probably take less if they had more wholesome recreation out of doors. Change of air and the cultivation of the love of nature, leading to exercise in fresh air, were recommended, but rapid locomotion might become a craze. The confirmed motorist became sluggish in intellect and excitable in temper, tending toward homicidal mania. The difficulties besetting sanitary inspectors were no longer what they were. When they exposed flagrant defects they were no longer, as in Ibsen's play, "the enemy of the people." They were the true and candid friends of the people, and as time goes on the people will more and more grasp and reward their friendliness.

Dr. John Henry Bell, consulting officer at Bradford Royal Infirmary and to the Eye Hospital, died suddenly on Sunday, from cardiac disease, aged seventy-four. He was M.D., St. And., 1861, M.R.C.S., 1857. He was much interested in anthrax, on which he contributed the article to Allbutt's "System of Medicine" and notes to the medical journals.

Dr. T. P. Cann has lost his life in an unusual way. He pricked his finger in an operation on the tonsils and streptococcal infection followed. He died on August 27, aged thirty-one. He was a Durham M.D.

Dr. Franklin H. Oliver, who died on the 22d ult., aged forty-seven, was chief district officer of the Royal Maternity Charity and surgeon to the City Lying-in Hospital. He also held other appointments and enjoyed an extensive practice.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CHOLERA—USE OF HUMAN EXCREMENT AS A FERTILIZER—A CHOLERA SERUM—BERIBERI AMONG LEPERS—SEGREGATION OF LEPERS—MISTAKES IN DIAGNOSIS—STUDY OF AN ERUPTIVE DISEASE IN GUAM.

MANILA, P. I., August 18, 1906.

THE outbreak of cholera, of which mention has been made in the last two letters, has not gained any considerable headway, the number of cases remaining about the same. The disease is being gradually eradicated from the provinces of Laguna and Rizal, but provinces not heretofore infected since the outbreak, August, 1905, are being gradually invaded, the provinces of Pangasinan and Benguet being the latest added to the list. So far, there has been no general infection of the water supplies at any point, and to this may be attributed the fact that the disease has not become epidemic, the infection being confined, in all probability, to foodstuffs. Occasionally a well becomes infected, but the prompt measures which are taken for its disinfection usually result favorably.

The disease in Manila, for the week ended August 11, showed a gradual decrease in the number of cases, but for the week ended August 18 a large increase has taken place. From August 1 to date there have been 159 cases with 137 deaths in Manila; and since July 1 there has been a total of 552 cases with 486 deaths. In view of the fact that a number of vegetable gardens were found during the last ten days which were being fertilized with liquid human excrement, and that the latter in all probability contained cholera organisms, it is not surprising that there should have been a sharp increase in the number of cholera cases in the city.

The mortality from the disease is gradually becoming lower; instead of 90 per cent. of the cases dying, as was the case during the last week in June, the rate has gradually gone down until it has now reached 69 per cent. at the San Lazaro Cholera Hospital.

One of the serious menaces which constantly confront the Philippines is the use of human excrement as a fertilizing material, it no doubt being responsible for the propagation of cholera, dysentery, and other water-borne diseases, and in view of the inadequate fines and punishments which are provided by existing law, the Commission, at a session held to-day, enacted a law making the use of such material for that purpose a penal offense. The act provides that: "No farmer, market gardener, or other person or persons shall use any human excreta, excrement, dejecta, or the contents of any water or earth closet, privy, vault, cesspool, latrine, pail, or other receptacle for human feces or urine, as a fertilizer for any land on which is grown any article or product intended for human food or human consumption, or allow any human excrement, excreta, or dejecta to be sprinkled on or applied in any manner or for any purpose to any crop, product, or vegetation growing on said land. Any person violating the provisions of this act shall, upon conviction, be punished by a fine of not less than fifty pesos nor more than two hundred pesos, or by imprisonment not to exceed six months, or by both such fine and imprisonment in the discretion of the court, for each offense."

About a week ago Dr. Denier, a bacteriologist connected with the Pasteur Institute of Saigon, arrived in Manila for the purpose of testing the value of a curative serum for cholera which has recently been prepared by him. So far, he has had an opportunity to try it with only a few cases, and it is entirely too early to state whether the serum has any value. The matter will be reported fully later.

Among the lepers that were recently removed to the Culion Léper Colony an outbreak of beriberi occurred, the mortality being particularly high. Investigation showed that while there were lepers from many islands at Culion, the beriberi has occurred only among those who were removed from the Cebú Leper Hospital. Since they suffered from beriberi at Cebú, it is quite probable that they carried the infection with them when they were transferred to the Culion Colony.

It is variously estimated that there are from four to five thousand lepers in the Islands. It is further estimated that it would require an expenditure of about 25 cents per capita per day by the Government for subsistence, material for houses, clothing, transportation, administration, etc., to maintain them all; in round numbers, an outlay of $400,000 (United States currency) would be required. The Government at the present time can scarcely support a fixed charge of this size. Fortunately, however, the geography of the Islands is such that the present finances and the demands of practical medicine can both be met and reconciled to a reasonable degree.

The plan is to remove all lepers from those islands which are well isolated, and at the same time have only comparatively few victims. In this way a large amount of territory, or area, can be freed of lepers at once. The principal source of infection being removed, there should be few persons attacked in these sections in the future, and the few cases that do occur can be immediately removed. The lepers from the islands of Minduro, Nasbate, Romblon, Tablas, Siquijor, Negros, Palawan, and Cuyo have all been removed.

One noteworthy fact was observed while lepers were being collected from the islands mentioned, namely: Only about one-half of those who were previously reported as lepers, were, on examination, found to be afflicted with the disease. If this same proportion should be maintained in the remaining islands, the number of actual lepers will be much smaller than has been estimated, and the solution of the leprosy problem would not be nearly so serious a matter as first appearances indicated.

It will now be very interesting to note whether further cases of leprosy occur in the islands from which they have now been removed, and if they occur with the same frequency as heretofore.

Dr. E. R. Stitt of the United States Navy, who started the laboratory at Cañacao which is maintained in connection with the Naval Hospital at Cavite, has gone to Guam for the purpose of making an investigation into the etiology of the eruptive disease found among the natives of that island, and of which so much has been written in the lay press.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 20, 1906.

The Winter Climate of Tucson, Pima County, Arizona.—I. W. Brewer gives a brief description of this locality. Most of the houses are built of adobe and are cool in summer and warm in winter. Temperature and humidity tables are appended. The place is essentially a winter station, as the summers are very hot and but few invalids are able to remain after the first of April. The lowest recorded temperature is 10° during a portion of the winter months. The relative humidity averages about 46 per cent. and varies but little from month to month. During the six months under consideration 66 per cent. of the days are liable to be clear and but 6 per cent. cloudy. Rain falls on an average of nineteen days. The prevailing direction of the wind is from the south, and the velocity averages between five and six miles per hour. There are occasional dust storms that blow with considerable force, but they are infrequent during the winter and fall. In winter Tucson has a higher temperature and lower humidity than many of the noted resorts in this country and abroad. It is a little cooler and dryer than Cairo, Egypt, although the rainfall is greater. Tucson is a desirable winter resort for persons in the early stages of tuberculosis, but not for advanced cases.

New York Medical Journal, September 22, 1905.

Danger of Weak Solutions of Carbolic Acid Used in Surgical Dressings.—L. B. Meyer makes a plea for the restriction of the sale of carbolic acid, setting forth that the present indiscriminate dispensing of carbolic solution is dangerous and declaring that physicians often order solutions of dangerous strength. Very weak ointments and solutions when applied to terminal parts often cause death of tissue and constitutional symptoms. He tabulates 22 cases of dermatitis, burns, superficial and deep gangrene following the use of preparations of ordinary strength. He declares that existing laws should be so reformulated as to forbid the sale of carbolic in any strength except on a physician's certificate. Solutions stronger than one-half of one per cent. may cause trouble if idiosyncrasy is present. Stronger applications can be made to carbuncles, in erysipelas, etc., than can safely be used on the fingers and toes.

Small, Frequent Meals in the Treatment of Certain Biliary Affections.—C. Herrman has observed in a case of biliary fistula the effect of the ingestion of food on the relative quantity of bile flowing into the duodenum through the common duct and that flowing into the cystic duct and out through the fistula. He noted the following facts: First, the amount of fistulous bile was greater during the night than during the day, in the proportion of about two to one. Second, when a meal was taken late at night there was very much less fistulous bile, the daily amount of bile secreted remaining approximately the same. These facts indicated that the ingestion of food had a decided effect on the amount of bile which passed into the duodenum. It was further noted that fruit and other substances which increased intestinal peristalsis also diminished the amount of fistulous bile. Alcohol seemed to act unfavorably by increasing the amount which escaped. The regular habit of tea drinking gave a disagreeable odor to the bile. Applying the principles thus suggested to the treatment of catarrhal jaundice, the author notes that the main object is to facilitate the bile flow through the common duct and to stimulate the gall-bladder to contraction. This, he believes, is best accomplished by the regular and frequent ingestion of food. His treatment consists in giving five or six small meals instead of the usual three daily, an extra one being introduced at 10 o'clock in the morning, at 4 o'clock in the afternoon, and at 11 o'clock at night. These small meals consist of milk, eggs, broth, crackers, or bread. If the patient awakes during the night, a glass of milk may be taken. The bowels are to be kept open by mild laxatives. A daily rectal injection of cold water is sometimes very efficacious. Light exercises, especially such as bring into play the diaphragm and the abdominal muscles, are helpful. In this way the writer has treated three cases of catarrhal jaundice in children with surprisingly good results. Within five days the urine and stools resumed their normal appearance, and in from ten days to two weeks the jaundice had disappeared.

Journal of the American Medical Association, September 29, 1906

Cirrhotic Changes from Injury to the Liver.—W. G. MacCallum notes the fact that the circulation of various poisons in the blood may cause focal or diffuse destruction of the liver cells. If limited in extent there may be no definite symptoms and the injured portion is replaced by scar tissue, the other portions being hypertrophied to compensate. If the cause persists, these changes may be continuous and finally result in one or other of the forms of cirrhosis of the liver. If the injury is very extensive, symptoms at once arise and a condition commonly classed as yellow atrophy of the liver may be brought about and quickly cause death, with great distortion of the liver. Such a case is here referred to. The object of the present paper, however, is to show that there is a scarred condition of the liver intermediate between the ordinary cirrhosis and the extreme distortion above mentioned, a condition, in other words, in which some single attack of infectious disease or some single intoxication has produced a single, nonprogressive, though widespread, injury from which complete and permanent recovery has occurred. Generally such livers show a smooth, even surface, interrupted only by a network of fine linear grooves indicating where the destruction of liver cells occurred. Elsewhere the lobules are normal, except for being a little larger than usual. These cases, when observed at autopsy, are commonly recognized as cases of incipient cirrhosis, but MacCallum holds that there is no evidence that the condition is part of a progressive process. It seems more probable that there is here a stationary condition differing from ordinary cirrhosis merely in not being progressive and representing only the scars of an old injury.

Cancer of the Lips and Tongue.—D. N. Eisendrath remarks that cancers of the lips, tongue, ear, etc., all belong to the squamous-celled type that extends almost exclusively by continuity of tissue or along the lymph spaces or vessels, and very rarely gives rise to metastases in distant organs. Hence the better chance of a permanent cure by early radical operation. For the less advanced cases as well as in the severer ones Eisendrath removes the lymphatic nodes and surrounding tissues in the submaxillary triangle and along the internal jugular vein as a routine procedure. At least a half inch of healthy tissue, or even more, on each side of the growth should be cut away, and in cancer of the tongue, if it extends beyond the median line, it is better to remove the entire organ, as the lymphatics on both sides of the neck are probably involved. Eisendrath insists on the importance of thorough removal of the deep cervical nodes along the internal jugular and on the necessity of avoiding infection of the field of operation, either from the primary growth or from the cancerous lymph nodes. The primary focus should be cauterized, if possible, and great care be taken to avoid opening the nodes. Eisendrath operates in cancer of the lips, face, and ear at one sitting, and he has done the same in cancer of the tongue in fairly robust patients without too much glandular involvement. If the latter is extensive it is better to follow Butlin's plan of operation in two stages.

Value of the X-Rays in Ocular Therapeutics.—G. O. Ring concludes that *x*-ray therapy is very promising in malignant disease of the eye. In superficial epithelioma and rodent ulcer of the eyelids it can usually be relied on, he believes, to effect a cure. He states that it is believed that good results obtained in certain cases of malignant disease of the cornea, conjunctiva, and caruncle will become general under more improved technique, and that the *x*-ray has proved of much value in the more extensive orbital carcinomata, though the results are less favorable the deeper the growth. Enough cures have been reported of lid and orbit sarcomata to warrant an exhaustive trial of the *x*-ray in this disease, more radical operative measures with subsequent *x*-ray treatment being indicated in case of primary failure. Ordinarily the rays have an anodyne effect in malignant disease of the eyelids and orbit, but in some cases exacerbations of pain have been reported from their use. *X*-ray treatment has been of benefit in trachoma, and there is testimony as to its value in vernal and chronic conjunctivitis, scleritis, episcleritis, traumatic uveitis, conjunctival tuberculosis, corneal ulceration, gloma, and gummata. Ring cautions against submitting cases to any but experts in *x*-ray treatment.

Temperature Taking in the Groin in Children.—A. H. Parks points out the advantages of taking the tempera-

ture of infants in the closed groin. The oral method is hardly practicable, and there are some dangers in the rectal method in the exposure and possibility of breakage of the instrument, as well as some other inconveniences and objections. He has made comparisons of temperatures taken by the different methods, rectal and inguinal, in 175 children, ranging between four months and five years in age, under identical conditions, and found that the average difference between the temperature of the closed inguinal fold and the rectum is 0.34° F. (0.18° C.), while the normal temperature in the former in the child is 98.5° F. The great facility of the inguinal method was very noticeable, as the natural close apposition of the thigh to the body retained the instrument in place and the retention of the thermometer in the groin was accomplished without any crying or uneasiness on the part of the child. In extremely emaciated cases it may be better to use the internal method, but when it is possible to use the external method the groin possesses decided advantages over the axilla.

The Lancet, September 15, 1906.

The Prophylactic Use of Antidiphtheritic Serum.—W. W. Shackelton records his personal experience in an epidemic occurring in a large school for boys. The usual dose employed was 2,000 units. Seven cases had occurred in a house holding 45 boys. No case occurred in this house after the first inoculation for five weeks except one, and that on the day after inoculation. One other case occurred in this house, but that was in the case of a boy (the only one who had not been injected). In another house in which three cases had occurred, inoculation stopped all further spread of the disease. All the cases (14) recovered. The article is a convincing exposition of the benefits of immunizing treatment.

Some Observations on Convulsions in Children and Their Relation to Epilepsy.—According to R. O. Moon, convulsions in early life may shade off indefinitely into epilepsy so that it is impossible to say where the one ends and the other begins. In an analysis of 100 cases fully one-half are shown to be without obvious cause. To such cases the name of idiopathic epilepsy is given. In the other half the first convulsion arose in connection with rickets, teething, trauma, specific fevers, indigestion, or indefinite ill health. A history of alcoholism was found in one or both parents in 10 per cent. of all cases, equally divided between the two varieties. The prognosis does not appear to be better in the cases originating in connection with some peripheral affection than with the others. There is an important element in all these cases other than the mere number of attacks. It is the mental and moral impairment of the patient. The starting point of some form of insanity may easily lie in uncared-for cases of convulsive tendencies. Frequently there are manifestations of nervous instability which indicate a radical unsoundness of the central nervous system as a more important factor in the production of infantile convulsions than is an extrinsic cause. Of drugs used in treatment special mention is made of urethane and chloral. It is possible that a convulsion may, regardless of its cause, have some effect upon the brain in the direction of setting up a bad habit, and render further attacks probable.

The Rash in Cerebrospinal Meningitis.—W. Wright says in commenting on some features of recent cases in Glasgow that in two instances a decided purpuric rash, purple in color and hemorrhagic in character as to the spots, with well-marked edges, was seen on the dorsum of the feet, but in no other area. In another case punctate hemorrhages appeared all over the trunk and limbs in scattered patches of six or seven spots. In still another case the rash appeared in crops at intervals of about seven days. On examination on the twenty-first day of the illness, purple and maroon spots, circular, with regular edges all the same size—*i.e.* that of a lentil—were seen on the dorsum of the feet, on the arms, the legs, the trunk (back and front), four below the chin, and one behind each ear. They were scattered over the body with areas of three to four inches of normal skin between each. These spots were definitely hemorrhagic in character and so well defined as to be seen from a considerable distance, the picture presenting quite the aspect of "spotted fever." Two days later these had almost disappeared, but others took their place.

The Pulse in Aortic Disease; the Relation of Pulse Curves to Blood Pressure.—T. Lewis analyzes 20 cases, giving a tabulated list of symptomological findings and reproducing a number of sphygmographic tracings. These must be examined in the original paper by those interested. Some of the most striking facts brought out in the study are the following: In 14 cases of an average age of thirty-six and one-half years there was an average systolic blood pressure of 132 mm. Hg. These cases were not associated with granular kidney; in 4 cases with chronic interstitial nephritis, average age 46 years, pressure was 136 mm. There was no definite relation between the pressure and the amount of arteriosclerosis and none between the pressure and amount of cardiac compensation. A pulsus bisferiens was palpable in 13 out of the 20. A definite relation existed between the height of the first secondary wave and the amount of arteriosclerosis; the greater the sclerosis the higher the wave, but there was no relation between the wave-height and pressure or compensation. A dicrotic notch was observable in all. It showed no definite relationship to the amount of regurgitation, arteriosclerosis, or compensation. The author comments on the difficulty of estimating blood pressure by palpation, and even by some of the sphygmographs, and states that many errors are current in the text-books regarding the interpretation of the curves produced on these instruments.

Suture of Perforating Heart Wound; Death on the Eleventh Day.—A patient of F. T. Travers fell and was impaled on the large spike of an iron fence. He managed to free himself, but fell and lay for some time without aid. Seen three hours after, he presented a transverse wound about two inches long over the lower end of the sternum, through which a vertical fissure in the bone could be seen. In addition there was the usual picture of collapse from hemorrhage. The wound was enlarged, exposing the lower half of the sternum on the left side; the vertical fissure extended upward to the second right costal cartilage, and there were fractures through the left half between the fourth and fifth and fifth and sixth costal cartilages; the portion between the second and fifth costal cartilages was missing. The third, fourth, and fifth cartilages were divided at their attachment to the ribs, and the lower fragment of the sternum was turned downward. In freeing the third cartilage the pleura was wounded. The rent, about half an inch in length, was at once clipped with artery forceps and closed by two sutures. A rent in the pericardium about two and a half inches in length was now exposed, through which blood was slowly escaping. The pericardium was full of blood-clot, which was gently sponged away; a piece of bone one inch by half an inch was removed, and a small spicule of bone was felt imbedded in the heart and extracted. On further examination a wound was felt in the right ventricle, and on following this along another piece of bone was felt. This was seized with forceps and removed, and its removal was followed immediately by a terrific gush of dark blood. The wound in the heart was at once plugged by the operator thrusting his finfiers in. The insertion of three fingers practically stopped the hemorrhage. He also found that his fingers were within the cavity of the heart, the index being separated from the middle and ring fingers by a band of tissue, which at the time he took to be the anterior flap of the tricuspid valve. Three sutures were inserted, withdrawing a finger as each was passed, and by them the wound was roughly drawn together, and then ten sutures were passed through the muscular coats, using the first three, which were left long, to steady the heart and bring the wound into view. A second row of ten Lembert sutures were passed through the pericardial serous coat, closing in the first row. The patient did well for a few days, but was very restless, and finally died on the eleventh day. Autopsy showed the wound in the heart well closed except at a small point where the muscle was necrotic.

Berliner klinische Wochenschrift, September 10, 1906.

The Surgical Treatment of Gastric Ulcer.—Rydygier took the occasion of the presentation of a patient on whom he had operated twenty-five years before for gastric ulcer by resection, to reiterate his conviction that this plan is preferable to gastroenterostomy in the treatment of ulcer of the stomach. While he admits that the resection operation is still technically more difficult than gastroenterostomy, he considers that this objection is more than counterbalanced by the advantage of removing completely the diseased area. A not unimportant drawback to the less radical procedure is the fact that the ulcer so frequently furnishes the starting point for a subsequent carcinoma, a danger that is obviated by resection. He concludes that the resection operation in those cases in which it can be carried out secures a more rapid and certain cure than any other

surgical procedure, since in addition to the improvement in the circulatory conditions it also removes the diseased tissues.

The Spirochete Question.—Friedenthal calls attention to the discrepancies existing in the descriptions of the *Spirochæta pallida* furnished by different observers, and also criticises the statements that the organisms can be demonstrated in large numbers in the internal organs of syphilitics after treatment of the tissues by a modification of Cajal's silver impregnation method as used in the study of the histology of the nervous system. The author believes that these structures, which have been interpreted by most observers as being spirochetes, are in reality artefacts such as nerve fibers or connective tissue fibers, and he illustrates a number of such pictures which he obtained in carcinomatous tissues. In another communication Schulze takes the same stand and illustrates structures resembling the conventional spirochetes which he obtained on inoculating the rabbit cornea with street dirt.

Munchener medizinische Wochenschrift, September 11, 1906.

Reflex Inhibition of the Renal Secretion During Cystoscopy.—Grund points out a danger of misinterpretation that attends the results obtained in renal diagnosis by the aid of cystoscopy with or without catheterization of the ureters. Just as stone occluding the ureter on one side can give rise to total anuria, the reflexes attending cystoscopic manipulations may also cause complete inhibition of renal activity. The author describes a case in which during a period of twenty-five minutes no urine at all entered the bladder of a patient suffering from tuberculosis of the bladder and kidneys while he was being examined by means of the cystoscope. The author says it is uncertain whether it is the irritation of the instrument or of the artificial distention of the bladder that gives rise to the reflex, though probably it is the stimulation at the neck of the bladder caused by both that originates the condition.

Epileptic Automobilists.—Thalwitzer proves that the danger of automobile accidents being caused through serious nervous diseases on the part of chauffeurs really exists, by describing two instances that have come under his own observation. In each case the driver of the machine came to grief on a straight road by suddenly turning his machine into the ditch, and was picked up unconscious and unable to explain how the accident had occurred. Investigation revealed the fact that each of the patients was an epileptic, and the occurrences point out the unwisdom of allowing such individuals to control motor vehicles.

The Treatment of Chronic Bronchitis by Means of the X-Ray.—Schilling gives the case histories of a number of patients suffering from chronic bronchitis and bronchial asthma whose condition was very considerably ameliorated by a single application of the *x*-rays. The radiation was carried out from various directions, during a period of ten to fifteen minutes, avoiding those parts protected by the thickest muscular layers. The most noticeable effect was the prompt reduction in the amount of bronchial secretion, which was very striking, and great relief also resulted from the cessation of the asthmatic attacks. While the author considers that the number of patients treated is still too small to permit of drawing very definite conclusions as to the value of the method, he is convinced that it has possibilities, and urges others to make control observations.

Deutsche medizinische Wochenschrift, September 13, 1906.

An Inhalation Mask for Producing Hyperemia of the Lungs.—Kuhn describes an inhalation mask which he has devised for use in cases of pulmonary tuberculosis in order to produce congestion of the lungs, basing his belief in the suitability of this form of treatment on the principles that underlie Bier's plan of treatment. The congestion is effected by restricting inhalation while expiration is unimpeded, and a model is described by means of which it is possible to demonstrate the greatly increased inflow of blood into the pulmonary vessels that must result under these conditions. The method does not involve increased activity of the lung itself, and therefore does not oppose the prevalent views in regard to the superiority of the rest treatment of the lung over that by pulmonary gymnastics. About forty patients have so far been treated by this method with very satisfactory results. The improvement in the general condition was both subjective and objective, fewer bacilli occurred in the sputum, and the cough was reduced in severity. An interesting observation was the fact that polycythemia and a rise in the hemoglobin percentage attended the use of the mask. There seemed to be no tendency to the production of pulmonary hemorrhages, and in ordinary cases there is no danger of overtaxing the heart. In advanced stages of the disease, in which the heart is already much weakened, the use of the mask would not be advisable, however.

The Behavior of the Spleen in Carcinoma.—Hollister investigated the condition of the spleen in one hundred and fourteen cases of carcinoma, of which sixty-one were of the stomach and nineteen of the esophagus. The others were of the bronchi, rectum, pancreas, biliary passages, a sigmoid flexure, uterus, breast, bladder, etc. The spleen was small, or at least not enlarged, in ninety-two cases and was enlarged in twenty-two cases. In many instances it was distinctly atrophic. The cases in which the spleen was enlarged presented some complication sufficient to account for the increase in size of the organ, such as chronic congestion in the portal system, severe general sepsis, or metastases in the spleen itself. The author concludes that the fact that the spleen undergoes no enlargement in the majority of cases of carcinoma is evidence against the infectious nature of the disease, and he considers that clinically it may be taken for granted that enlargement of the spleen is rare in carcinoma and when it exists depends on the presence of some complication. In doubtful cases of hepatic disease splenic tumor is against carcinoma, while its absence speaks in favor of malignant disease.

French and Italian Journals.

Yellow Fever.—Marchoux and Simond made most interesting observations during the time of the French expedition which was sent to Rio de Janeiro to study this disease. The frequency of abortion in pregnant women attacked by yellow fever tends to show that the mother can transmit the disease to the fetus. This fever can attack the infant in the first months of life. Relapses are rare, but when they occur they are in general very grave. The *Stegomyia fasciata* is the transmitting agent of yellow fever. This insect can inoculate the disease by its bite after it has itself become infected. It contracts the disease by biting patients on the first, second, or third day of the disease. Sometimes, the authors maintain, the disease can be transmitted from the insect mother to its young by heredity. This hereditary transmission does not pass beyond the first generation. During the period when the mosquito possesses the infecting power it does not try to bite a human being between the hours of 7 in the morning and 5 in the evening. Prophylactic measures should be practised in relation both to the mosquito and to the patient. The insects should be exterminated and human beings should be protected from bites, especially during the night.—*La Tribune Médicale,* September 1, 1906.

The Healing of Aseptic Wounds of the Brain.—Da Fano has made careful experiments on animals to determine the part taken in the repair of brain tissue by the connective tissue and the neuroglia. The scars examined were produced by lesions made experimentally with removal of a small amount of brain tissue, in the brains of rabbits and dogs. The connective tissue and neuroglia take different parts in the repair of tissue, according to the length of time since the wound. At first the connective tissue takes the whole office of repair, the nerve elements undergoing degeneration; later a marginal layer forms of nerve tissue, with fibers predominating. Still later, in consequence of the retraction of the cicatrix, the relations between the connective tissue and the marginal nerve layer become more complex and an interlacing of connective tissue fibers and nerve fibers takes place of a complicated nature. The neuroglia in the cicatrix is formed of cells with protoplasmic prolongations in which a fibrillar portion is differentiated from the cytoplasm. It has not yet been determined whether it contains nerve fibers independent of the cells.—*La Riforma Medica,* July 14, 1906.

Harmlessness of Dust Made from the Desiccation of Tuberculous Sputum.—Cadéac declares that the dust ground from dried tuberculous sputum is harmless both to the digestive and to the respiratory passages. Not a single experiment has shown the transmission of tuberculosis by the inhalation of dust gathered from localities inhabited by tuberculous patients. The writer has demonstrated that it is almost impossible to cause the development of this disease by the inhalation of this infected dust. The desiccation and the rapid conversion of sputum into flying dust are the natural means of preservation against tuberculous infection.—*Le Bulletin Médical,* September 5, 1906.

Book Reviews.

Les Empoisonneuses. Étude Psychologique et Médico-Légale. Par le Dr. René Charpentier, Ancien Externe des Hôpitaux de Paris. Interne des Asiles d'Aliénés de la Seine. Paris: Steinheil, 1906.

Charpentier's thesis deals with the famous women poisoners of all ages from the viewpoint of the alienist and the criminologist. A historical review of the principal women poisoners of antiquity and the Middle Ages, beginning with the mythological Hekate, queen of Colchos, down to Lucrecia Borgia and the Marquise de Brinvilliers, forms the first part of the book. The second portion is devoted to clinical and biographical studies of modern poisoners, who are classified as (1) hysterical degenerates, (2) poisoners with melancholic tendencies, (3) poisoners who simulate insanity, and (4) falsely accused poisoners. The author concludes that poisoning is peculiarly a woman's crime; that it is the favorite weapon of hysterical women; that these women are always physically and mentally degenerate, and that they should be confined in asylums instead of being condemned to death. Dr. Charpentier has contributed an excellent monograph on an extremely interesting phase of psychiatry and criminalogy, and his book will find a place in the library of both lawyers and physicians who are interested in the psychology of poisoners.

The Autotoxicoses; Their Theory, Pathology, and Treatment. By Heinrich Stern, Ph.M., M.D., New York, Professor of Special Medical Pathology and Therapy in the College of Physicians and Surgeons, Boston; Director of the Institute for Medical Diagnosis and Research in the City of New York; Physician-in-Chief, Philanthropin Hospital in the City of New York; Pediatrist and Pathologist, Misericordia Hospital and the Hartsdale Infirmary; Consulting Physician, Metropolitan and Red Cross Hospitals; Chairman Section on Pharmacology, American Medical Association; Permanent Member Medical Society State of New York; Fellow of the New York Academy of Medicine, etc., etc. Chicago: G. P. Engelhard and Company, 1906.

The present volume is the latest addition to the literature of autointoxication. The subject is, naturally, of the greatest importance, and the author endeavors to show that certain phenomena are due to the absorption of poisonous metabolic products. He also contends that autointoxication is not as common as is generally supposed, and that the condition when present is hard to demonstrate. Dr. Stern's book is divided into two parts; the first contains a brief historical epitome, which is followed by chapters on autointoxication in general, intestinal autointoxication, catabolic autointoxication, critical considerations of the autointoxications, the physicoautotoxic state, and the pathogenesis of uremia. There is also a chapter containing recapitulation and conclusions. Part Two deals with the treatment of intestinal and catabolic autointoxications. In the appendix is a glossary, which is very necessary in view of the terminology adopted by the author. To use the terms carbamid and tartronyl cyanamid for the more familiar words urea and uric acid tends to confusion and serves no good purpose. There is so much of value in the book, that it is a pity the author has made it difficult for the reader to profit by it.

Aids to Surgery. By Joseph Cunning, M.B., B.S., F.R.C.S. Eng., Senior Resident Medical Officer Royal Free Hospital. New York: William Wood and Company, 1906.

This is a volume of the new Students' Aid Series, and can be recommended as a first-class *résumé* of the main principles and facts of surgery. The arrangement follows closely that of Rose and Carless' Manual of Surgery, and a better guide the author could not have selected. To students in college this book will save the drudgery of taking notes; and to all who have to face a written examination in surgery this little book will prove of incalculable service. The work contains thirty-nine chapters, and within the compass of 384 small pages the author has managed to compress all the essentials of surgery. It is concise, accurate, and unusually complete.

Clinical Bacteriology and Hæmatology for Practitioners. By W. D'Este Emery, M.D., D.Sc., Lond., Clinical Pathologist to King's College Hospital, etc. Being the Second Edition of "A Handbook of Bacteriological Diagnosis for Practitioners." Philadelphia: P. Blakiston's Son & Co., 1906.

The highest compliment that can be paid to a medical book nowadays is to say that it fills a distinct want. The present volume will supply the increasing demand for a practical manual of bacteriological and hematological examinations which excludes everything but what a practitioner needs. Emery's book is written evidently by a teacher who has had to supply information to post-graduate practitioners in the most practical, direct, and boiled-down form possible. The text covers the elementary technics of bacteriology, the bacteriological diagnosis of disease, the examination of pus, saliva, throat secretions, conjunctiva, sputum, gastric contents, pleural and other exudates, and the blood. Concise directions for fixing, hardening, embedding and cutting sections are also given. Hematology is treated in forty pages of pithy matter and a chapter on cytodiagnosis is appended. The two plates on the blood (VII and VIII) are not only true to life, but sufficiently diagrammatic to constitute a useful summary of the different types of cells, the method used being to portray a single typical cell of each kind. The other colored plates are also of a high character. The book is thoroughly up to date, containing, for example, descriptions of the macroscopic methods for typhoid fever diagnosis and the detection of *Spirochæta pallida* of Schaudinn; Wright's opsonic blood reaction, etc. As a rule a single method of procedure is given for each examination, the selection of stains, etc., being usually very practical, this mode of writing doing away with the bewildering array of methods usually found in text-books.

Collected Studies on Immunity. By Prof. Paul Ehrlich, Privy Councilor and Director of the Royal Institute for Experimental Therapy, Frankfort, Germany, and by His Collaborators, with Several New Contributions, Including a Chapter Written Expressly for This Edition by Professor Ehrlich, Translated by Dr. Charles Bolduan, Professor of Bacteriology and Hygiene in Fordham University, New York; Assistant Bacteriologist, Research Laboratory, Department of Health, City of New York. New York: John Wiley and Sons; London: Chapman and Hall, Limited, 1906.

This invaluable collection of the immunity studies of Ehrlich and his collaborators presents to the English reader for the first time a consecutive history, as it were, of the wonderful developments along the lines of Ehrlich's ingenious theory of immunity. The nomenclature employed by the German, French, and English investigators who have worked along the lines indicated by Ehrlich and which by reason of its confusing synonyms has made the subject a difficult one for the ordinary medical reader, is no longer a stumbling block as presented in this series of studies collected and translated by Bolduan. As already stated, the translator has arranged this collection of studies consecutively. The volume consists of forty chapters, each one being a more or less independent contribution to the subject and representing the work not only of Ehrlich and Morgenroth, but that of von Dungern, M. Neisser, Lipstein, Rehns, Sachs, Proscher, Marshall, Korschun, Kyes, Shiga, and Marx, and a forty-first chapter presenting a general review of the whole subject written by Ehrlich himself expressly for this translation. This volume, therefore, brings the subject up to the present year and is indispensable to the student and worker in this field, especially when he does not read German. The convenience, moreover, of collating the whole subject so succinctly between the covers of one volume is a great advantage. The charts and tables are extremely interesting, and the diagrams illustrating the ingenious side-chain theory are of infinite assistance to the comprehension of the text. It may be safely said that this volume constitutes one of the most important and valuable contributions of the year to English medical literature.

The Urethrotomies and Kidney Capsulotomy in Diseases and Injuries of the Urinary Organs. By Reginald Harrison, F.R.C.S., etc. New York: William Wood and Company, 1906.

This book is based on a series of clinical lectures given by the author and represents in a way his most recent views on the subjects in question. The writer has been connected intimately with the development of these branches, and his text is therefore authoritative. The entire subject of urethrotomy is discussed in a brief yet thoroughly practical manner, but the general interest will probably be centered on the chapter on capsulotomy, which operation the author was among the first to advocate for the relief of inflammatory affections of the kidney. Harrison claims that it is sufficient to incise the renal capsule in order to relieve the tension in the organ, and does not think it necessary to strip back or remove part of the capsule after the manner of Edebohls. Harrison believes that the operation of capsulotomy as advocated by him has been shown by experience to warrant its adoption in suitable cases, and thinks that more attention should be given to the subject of tension in the earlier stages of kidney inflammation and its relation to circulatory complications. The book contains but 96 pages, yet every one is interesting and instructive.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held at Niagara Falls, May 31, June 1 and 2, 1906

THE PRESIDENT, DR. JOSEPH W GLEITSMANN, IN THE CHAIR.

President's Address.—Dr. GLEITSMANN delivered this address (see page 57)

How Far are Abnormalities of the Nasal Septum Responsible for Malfunction of the Nose?—Dr. HENRY L. SWAIN of New Haven, Conn., described the usual provisions of nature for keeping the nasal passages free from irritating and harmful materials. Macroscopical particles are taken care of with comparative ease, but we do not know as much about microscopical particles. In the latter instance the protecting duty falls on the cells, whose chemical or phagocytic functions are called into play. The protective system may be rendered useless by deformities of the nasal skeleton, which render ready cleansing by sneezing and blowing and the free downward flow of fluids practically impossible. Under these circumstances bacterial growth in the nose may occur with great rapidity. The nasal integrity depends, after all, on the condition of the epithelial cells on the outer wall. Concerning the protection against subtle chemical, electrical, and other irritations, we are largely ignorant of the manner in which nature works. Nor, moreover, do we know just how and why the vital cells know and appreciate what is harmful and what harmless. A solution of this riddle gives the key to all physiological phenomena. As a result of repeated attacks of acute rhinitis a chronic change is set up, and the protective mechanism becomes permanently impaired. The author does not think it logical to lay all the blame of this impairment, as is commonly done, on the nasal septum. Its influence in states of deviation from the normal perpendicular has been overestimated on nasal function. Septal deviations are often the outcome of inherited facial asymmetry, or arise from exaggerations by the accidents of disease, neglect of teeth, trauma in youth, etc., yet many patients having the misshapen septa live ordinarily long lives without any more nasal disturbance than is experienced by patients having comparatively straight septa. The present views as to the relation of septal abnormalities to nasal malfunction are the natural result of the teaching of recent years. If the septum is so bent as actually to interfere with breathing, there is no doubt as to the course to be followed, but whatever we do, we should accomplish the desired result by as mild measures as possible, with little destruction of the normal epithelium and with as good preservation of the normal anatomical relations as possible. The author stated that he could not make it seem right to remove turbinal tissue when an exostosis was at fault. It might be easier, but it was not logical. Neither was it right to remove turbinal tissue when the problem was to make crooked septa straight. Yet after much experience, we are sometimes met with the fact that, although we may have done at the time what seemed best in our judgment, the catarrhal condition for which relief has been sought has not been greatly benefited. We should not fall into the habit of laying the whole fault for the catarrh on a slight septal bend. The catarrhal condition is referable in part at least to the conditions of modern life, dry heat, narrow apartments, late hours, busy work, etc. Often, then, the main thing to bring about is an alteration in the manner of living and a change in environment. If we confine ourselves to surgical intervention, our ultimate results will be disappointing. We may straighten the septum, plane it off, smooth it down, but yet hypertrophy will return, annual catarrhs continue, and sinus disease occur in spite of all.

Some Observations on Nontraumatic Perforations of the Septum.—Dr. CHARLES W. RICHARDSON referred to cases without a known etiological factor and with an indefinite pathological history. In none of this group could the exciting cause be the irritation from acids or chemicals. In only a few was there any history of obstruction. We know that when the anterior inferior portion of the septum is injured, nature's efforts at repair are very unsatisfactory. In addition to the exposed situation of this area there seemed to be some additional constitutional condition lessening the normal nutritive activity of the affected structures, so that ordinary irritation worked an unexpectedly great destruction. Such a constitutional influence is seen in typhoid fever, for instance, and the author believed that in the tuberculously inclined especially there was something imparted to the tissues, especially those of the fibrous and epithelial type, which rendered them, when the nutritive changes were impaired, liable to retrogression and destruction. In an analysis of fifteen personal cases, there was found in eleven either direct physical evidence of tuberculosis in the patient or there was a definite family history of this diathesis. Findings made on the cadaver by Weichselbaum and Hajek confirmed the view taken. Many cases of septal irritation were not followed by perforation. Many endure for years, some heal, and some may perforate, but tuberculosis and the tuberculous diathesis impress on various tissues of the body such alteration in their nutritive processes that when the proper stimulus is applied they lead to degenerative changes which may or may not show the characteristic histological elements of tuberculosis.

Nasal Skiagraphy.—Dr. CORNELIUS G. COAKLEY of New York City gave an exhibition of skiagraphs, showing various diseased conditions and anomalies of the nasal accessory sinuses, and described the technical methods employed in their production. He was of the opinion that while in certain instances the results of this method of diagnosis might be very uncertain, yet in other instances it afforded us very definite information as to the size, shape, and relations of the sinuses, and gave us also very definite knowledge as to the condition of the mucous lining.

The Ultimate Results of Radical Operations Upon the Accessory Nasal Sinuses.—Dr. D. BRYSON DELAVAN of New York commented on the fact that relief had not always been finally afforded by radical operation, that the progress had often been painfully slow, and the ultimate outcome unsatisfactory and disappointing. Unsuccessful cases are not often reported, and statistics calculated to show the relative values of different methods of operation are not attainable. There have been notable exceptions to this rule in the case of the work of some members of the Association, who have frankly stated their actual results. In some instances the nasal cavity has assumed a condition to all intents normal as to sensation and function, yet the patient has been unaware of any unusual change in it, and the progress of time has been unmarked by semblance of accident or relapse. In other cases the results have not been so fortunate. Sometimes the cure itself has been incomplete, or, again, new foci of disease have developed, at times long after every probability of their appearance has passed away. The ultimate condition is a subject which apparently has been studiously avoided. It cannot be denied that the results in many cases have been brilliant and permanent, but sometimes the formation of crusts persists for years after intranasal operation. The undue widening of the nasal cavities may cause the many unpleasant symptoms due to the too free admission of air. A better knowledge of all these results is highly desirable, because (1) if the seriousness of the situation has been overestimated, it is well that we should be reassured; (2) if it has not been overestimated, the best means for its prevention should be studied and applied. Most important of all, through a clear understanding of the dangers, difficulties, and discomforts of these

more radical cases, the profession will be led to appreciate and thus reduce to the lowest possible number the cases of acute sinus disease and early recognition and efficient treatment of it when it has once appeared, cure the conditon and thus reduce to the lowest possible number the cases which have become fully and hopelessly established as chronic. The establishment of necrosis calls, of course, for the removal of offending tissue. Great responsibility rests upon the practitioner who first sees the case, particularly during grippe seasons, when so much can be done to make the patient comfortable, lessen the severity of the inflammation, and prevent the establishment of the later features of neglected sinus disease. So also the possible influence of a specific factor in a given case should lead us to administer the iodide, neglect of which precaution may lead to widespread disaster. In any event, reasonable conservatism in operation and prolonged observation of every case are factors which are indispensable.

A New Operation for Extreme Cases of Septal Deflection, With Presentation of a Successful Result in an Adult Patient.—Dr. J. Price-Brown of Toronto made a plea for the retention of the substance of the septum and was not inclined to grant all that the advocates of the submucous resection claimed for the latter procedure. Many cases of perforation had been reported, even in the hands of skilled operators. We do not know what will be in future years the condition of these resected septa. We do not know how the latter will stand the aridity of fevers, typhoids, and pneumonias. Therefore the ideal result would be to so act on the septum as to relieve it of all tension without removing it, and to replace it with perfect healing in the central plane. The author has been in the habit of making two longitudinal cuts with a thick saw from before backward through the septum, making them from the convex side, about half an inch apart, passing through both mucosa, the lower cut being just above the superior maxillary ridge. Rubber splints were then employed to hold the septum in the correct position. Results were fairly good, but the cuts did not destroy the central resiliency of the large curvature from before backward. Therefore the author had joined the two incisions by a third one at right angles to them, and the operation might be called the "H" operation. The points to which he wished to draw attention were these: First, that as the curvature of the cartilage from above downward gave it a greater width than it could occupy if it were upright in its normal position, the two longitudinal cuts should be so managed as to remove two long slips of the septal cartilage and at the same time be made at an oblique angle, so that the cut edges could slide over each other; second, that the cross of the "H" should be very decidedly oblique, extending at right angles beyond both of the other and parallel incisions, and cutting through both mucosa and cartilage, so that in replacing the segments the posterior central segment would slide forward over its fellow and the anterior one backward. It matters little how these cuts are made if the principle on which they are founded is carried out. (The clinical history of the case was then read and the patient was examined by the gentlemen interested.)

Dr. Emil Mayer thought that Dr. Brown's operation was mechanically a double Asch operation. On general principles he was of the opinion that the submucous operation is the best one yet devised. Cases should be selected, however. He had been unable to operate satisfactorily in this way on very young children, and had not been able to secure good anesthesia, when it came to working on the bony portions, from cocaine alone. One case was mentioned of cocaine intoxication.

Dr. Otto T. Freer championed the submucous operation, and said he had had no difficulty with children, even under local anesthesia. He had examined Dr. Brown's patient and did not feel satisfied with the result. The more he operated the more inclined he felt to use sharp rather than blunt instruments, as he believed the former less painful. He also believed that the submucous operation was applicable to every possible form of deflection.

Dr. C. F. Theisen employed general anesthesia in children under fifteen years, using the recumbent position and strong electric illumination. If the deviation was confined to the cartilaginous septum, the Asch procedure was good, but if the bone was involved the submucous operation would give better results.

Dr. J. O. Roe believed that a great many submucous operations were being done unnecessarily. He, too, would regard Dr. Brown's operation as a modified Asch.

Dr. C. W. Richardson did not believe that Dr. Brown's operation would give satisfactory results in many cases. He failed to see how it could produce a perfectly straight septum. He had been won over to the submucous operation, though not particularly enthusiastic over it at first.

In closing the discussion, Dr. Brown justified the positions taken in his paper. As long as we had normal tissue present it was our duty to replace it in the proper position, rather than to remove it. He referred to certain mechanical principles involved in septal reposition. In his patient, the results, so far as personal comfort and restoration of nasal function were concerned, were most satisfactory.

The Ethmoturbinal Cells, Clinically Considered.—Dr. John O. Roe of Rochester discussed the theories as to the mode of formation of these cells in the middle turbinate body and enumerated the symptoms caused by their distention. We might have pressure symptoms or troubles of a reflex nature. The enlargement of the bone caused by the distended cell was often mistaken for a polyp. The cells were often the seat of an empyema, and the source of the pus was erroneously looked for in some one of the accessory nasal sinuses. The condition could be differentiated from enlargement caused by growths, cysts, or simple turbinate tissue hypertrophy by the use of the probe. Puncture of a supposed polyp might reveal the exact nature of the growth. Treatment should consist in the removal of all pressure and the restoration of nasal patency. Removal of the entire turbinate might be necessary, especially if the condition were associated with disease of the posterior ethmoid or frontal cells. If the outer wall of the cell is thin it may be forced inward, thus leading to a collapse and obliteration of the cavity in the turbinate.

Frontonasal Encephalocele.—Dr. Frederic E. Hopkins of Springfield reported the history of a case of this nature. A child of eleven months was brought to him with a small swelling over the right nasal bone. It was congenital and had been regarded as a cyst. The fossa on that side seemed obstructed and seemed to contain constantly a clear, watery fluid. Polyps had been removed from this side three months previously, giving but temporary relief. Dr. Hopkins found a mass in the right naris, extending to the depth of half an inch and apparently attached to the outer wall near the end of the inferior turbinate. This was removed without incident with a cold wire snare. Examination now revealed a globular tumor at the level of the middle turbinate, about five-eighths of an inch in diameter, perfectly smooth, of a grayish color, and semitransparent. Pressure on the swelling in the naris caused an increase of the swelling over the nasal bone outside. Diagnosis of cerebral hernia was made and nothing further done at the time. The naris now dropped cerebrospinal fluid at the rate of about four drops per minute. The child became ill on the fifth day and died of meningitis at the end of two weeks. The report of the pathologist on the tissue removed was to the effect that it was doubtless a part of the meninges, as it contained more fibrous tissue and cellular elements than an edematous polyp, which it was first supposed to be.

Diseases of the Trachea.—Dr. James E. Newcomb of New York opened "A Symposium of Diseases of the Trachea," taking up the subject of Abnormalities, Hemorrhages, Inflammations, and Infections. A plea was made

for a more extensive use of the mirror in examining the trachea. Various malformations were briefly described. Perichondritis was generally secondary to some infection, as typhoid, tuberculosis, or syphilis. Various dermatoses might occur, such as erythema nodosum, herpes, impetigo herpetiformis, erythema multiforme, lichen ruber, and angioneurotic edema. Acute catarrh was generally associated with that of the larynx and bronchi. Dysphagia had been by some authors regarded as a symptom of tracheal inflammation. New methods of tracheal injection were touched on, such as that of Marangos, who injects through the nose, and Mendel, who projects the fluid against the side of the pharynx, whence it runs down into the trachea. Ozena might occur primarily in the tube, and several instances of severe stenosis were on record from crust accumulation. Nothing new had been advanced as to the etiology of this affection. Tracheal hemorrhage had been reported by numerous writers, and generally as a sequel of influenza. It was necessary to follow up such cases, as they might eventually become tuberculous. But there were cases in which the blood could be seen to ooze from varicose vessels just below the glottis, while the rest of the tracheal walls were perfectly clear. Tuberculosis was generally a feeble episode only, in the laryngeal and pulmonary disease it accompanied. Primary tuberculosis of the trachea, however, had been observed. True tuberculoma of the trachea had been described twenty-five years ago by J. N. Mackenzie, but few authoritative cases were on record. Syphilitic lesions found in the trachea comprised catarrh, erythema, condyloma, ulcers, perichondritis, cicatrices, and gumma. Infiltration in this region might be delayed for years. The use of the bronchoscope as recently developed offered the possibility of a greater definiteness of localization of lesion. Each case called for treatment constitutionally and mechanically, according to its special requirements. It was difficult in clinical practice to separate syphilis of the trachea from that of the bronchi.

Tracheal Tumors.—Dr CLEMENT F. THEISEN of Albany, N. Y., presented a paper based on a study of most of the authentic cases of primary tracheal tumors on record, 135 cases being considered. Of these 89 were benign and 46 malignant. Of the former, the varieties found comprised fibroma (polyps), lipoma, papilloma, ecchondroma and chondroosteoma, adenoma, intratracheal struma, and lymphoma; of the latter, carcinoma and sarcoma. Particular attention was given by the author to intratracheal struma, ten cases of which were now on record. The majority of papillomata occurred in children and were undoubtedly congenital. Only one genuine case of lipoma is recorded. Two cases of lymphoma and seven of adenoma were considered. Twenty-four cases of fibroma were found, fifteen of which were pedunculated. In the majority of cases they occurred during middle life. Very little was known as to the genesis of ecchondromata and chondroosteomata. Of the malignant growths, primary carcinoma occurred most frequently in the medullary form, but occasionally as a cylindroma. In a number of instances the growth originated in the tracheal mucous glands. One case seemed to be a malignant degeneration of an original strumor, and in this case an extensive resection of the trachea was performed. Cancer favors the male sex. Of sarcoma, the author had been able to find records of eighteen cases. While endotracheal operations have been performed several times, they offer little chance of permanent success. The sexes suffer alike in this form of malignancy, young people rather than old. The author then discussed the etiology, symptomatology, diagnosis, and treatment of tracheal tumors in general. An extensive bibliography was appended.

Tracheal Stenoses.—Dr. WILLIAM K. SIMPSON of New York City enumerated as the extrinsic causes of stenosis, struma, pressure by tumors, glandular hypertrophies, emphysema pressure, aneurysms, phlegmonous inflammations of cellular tissue, extension of bone disease, trauma; intrinsic causes were classified as cicatrices and adhesions, morbid growths and foreign bodies, inhalation of irritants and ingestion of corrosive chemicals, and inflammations leading to thickening of the tracheal walls. The author then discussed the mode of action of these various causes in detail, and enumerated the symptoms caused thereby. The especial symptom was the stridulous breathing. Tracheal dyspnea had some characteristics peculiar to itself. It was inspiratory in character, the inspiration being longer than expiration; might be labored, noisy, or wheezing, was at times audible for a considerable distance, but had not the peculiar brassy, croupy, stridulous sound of laryngeal dyspnea. Diagnosis could be made by the laryngeal mirror, aided in obscure cases by the *x*-ray. Operation revealed a greater extent of stenosis than would be indicated by the mirror image. Treatment depended on the recognition of the cause. Outside of specific cases it was entirely surgical. We had at our command tracheotomy, tracheal fissure, with exsection of the stricture tissue, resection of the portion of the trachea involved, and finally the various forms of dilatation. Dr. Simpson showed various models of cannulæ employed for the last-named purpose.

Foreign Bodies and Tracheoscopy.—Dr. A. COOLIDGE, Jr., of Boston spoke of the behavior of foreign bodies drawn into the upper air passages, and said that the important question, after considering the nature of the body, its probable position, and the patient's general condition, was, what is the danger of leaving it alone; next, if an attempt at removal was made, was the patient's chance improved or not; and, finally, what operation should be done? Various statistics were quoted, but the proper methods of treatment adopted during recent years rendered an entirely new consideration of all the foregoing points necessary. The author briefly traced the history of tracheoscopy and bronchoscopy, and discussed the physical principles involved. In the older methods the surgeons worked in the dark; with modern instruments, he could see just what he was doing, and inspection of the trachea and bronchi became just as definite a procedure as inspection of other bodily areas requiring special instruments. Modern essentials were a proper tube, a good illumination, and an instrument for extraction of the foreign body which could be easily and safely used through the tube. The author submitted various instruments, and spoke of certain modifications in their employment which had proven of service to him. In closing, he reported three cases, in addition to the five previously reported to the Association. The foreign bodies were respectively a prune stone, shingle nail, and hook. All were successfully removed.

Dr. EMIL MAYER had had five personal cases of bronchoscopy, and expected to publish shortly a record of his experience. In one of these cases a melon seed had been removed from a child of ten months. As far as he knew this was the youngest case on record. The introduction of the tube was sometimes very difficult.

Dr. E. FLETCHER INGALS had found some of the instruments on the market clumsy, if not even dangerous. He had done the upper operation some twelve or fourteen times and the lower once. He was in doubt as to the advisability of using cocaine or atropine in these cases. There had been some unaccountable cases of death following a successful operation.

Dr. J. SOLIS-COHEN thought that stenoses following tracheotomy often arose from the fact that the operation was done too high up. He had adopted the practice of using two tubes, one long and the other short. These were changed frequently, so that the irritation from pressure did not constantly bear on the same spot. Tubes flattened laterally were preferable to round tubes.

Dr. D. BRYSON DELAVAN believed that damage was sometimes done to the vagus through too much manipulation of

these regions. Such damage might explain some of the mysterious fatal cases.

Dr. THOMAS HUBBARD had found that rings of cicatricial tissue sometimes formed after operation, causing dyspnea.

Dr. THOMAS J. HARRIS said that dyspnea was sometimes hard to account for, as no stenotic ring could be found to explain it.

Dr. JOHN O. ROE called attention to the fact that in his experience those who had had a tracheotomy done in their childhood rarely reached an advanced age.

Dr. J. W. GLEITSMANN said that the tubes in halves which Dr. Coolidge had shown had been known to turn over each other, thus rendering the manipulation of the bronchoscopy tubes very difficult.

Dr. W. K. SIMPSON said that small bodies were often expelled through the short O'Dwyer tubes by the act of coughing.

Dr. C. F. THEISEN referred to a recent publication by Schroetter, describing a bronchoscope devised after a new principle. It had been described in a recent issue of the *Wiener medizinische Wochenschrift*.

Fibroma of the Larynx in a Child of Five Years; Apparent Cure; Recurrence as a Papilloma; Laryngofissure; Cure.—Dr. THOMAS J. HARRIS of New York gave the later history of a case which was originally reported to the Association one year ago. The sequence of later events is indicated in the title. The stenosis returned in about six months after she had seemed cured, and appeared to be granulomatous in nature, but the microscope showed it to be papillomatous. A tube was then worn for about six months longer, since which time the larynx had been free. The voice, however, was gone. A fair view of the larynx could now be obtained with the short Killian tube, and while there was no evidence of any neoplasm, there was very little cord remaining.

Hysterical Mutism.—Dr. G. HUDSON MAKUEN of Philadelphia gave a general description of this condition. He also reported the case of a young man of twenty-two years who was struck across the bridge of the nose and right orbit by a live trolley wire. He was dazed for a few hours, but apparently not severely injured. The power of speech, however, was in complete abeyance. When coming under the author's observation some time later, several minor faults of the upper air passages were removed, without any effect on the loss of speech. There was marked anesthesia in the larynx. The patient could not hold the vocal cords in approximation sufficiently to make them vibrate and produce sound; he could not produce either resonant or whispered sounds, and did not seem to know how to begin to try, lacking the mental conception of articulative movements as well as that of movements for vocalization. Instruction was carried on for some weeks, with the result of the acquirement of a few short, partly-whispered words, but the patient soon forgot what he had apparently acquired. There was a "psychological lesion" in the center for motor speech. All sorts of laryngeal stimulation were tried for some time. During the fourth month of his illness he had two typical hysterical seizures, and during the second one, which was very severe and happened at night, his silence of fifteen months was broken, though his first words were uttered in a state of unconsciousness. He was gradually awakened and talked constantly. From that time on progress was satisfactory, though for a considerable period he was troubled with various nervous symptoms.

Papilloma of the Larynx From Inhaling Flames.—Dr. A. B. THRASHER of Cincinnati presented the history of this case. His patient, a man, had been injured two months before coming under observation by an explosion of gas in the cellar of a drug store. He had had a severe inflammation of the upper air tract, from which he had made a slow recovery and had gradually become aphonic. Examination revealed in addition to a general redness of the parts several granulomatous-looking masses springing from the ventricles and almost obstructing the entire cords. Other similar bodies were seen below the cords during forced inspiration. Examination of a fragment removed revealed a papillomatous neoplasm, with some admixture of granulation tissue. The masses were removed a few at a time, bleeding following each seance being rather profuse. Silver nitrate, 10 per cent., was applied to the base of each nodule. A few months later the larynx was sufficiently cleared to allow of a view of both cords, and his voice became considerably stronger. Still later the voice became normal, though no later view of the region was had. The author noted that so far as this one case went, it lent favor to the theory of the inflammatory origin of laryngeal papillomata.

Scleroma of the Larynx.—Dr. EMIL MAYER of New York City reported one personal case, his patient being a Russian Pole, girl, aged sixteen years. While crossing the ocean three years previously she took cold and became hoarse. Hoarseness had remained constant. Masses of crusts were expelled, together with much secretion from the nose and nasopharynx, and there had been an increasing dyspnea. Odor was absent, and the general health had continued good. Some of the crusts were removed and sent to the pathologist, who reported that the condition was scleroma. Dr. Mayer reviewed the literature of the subject, epitomizing the statements of various authors. Dr. Mayer stated that the prognosis as to recovery was bad, though the general health might not be impaired save from such symptoms as the varying stenosis would occasion. External conditions had been benefited by the *x*-ray. In the larynx, removal of the crusts was often necessary. The pressure of an intubation tube both before and after tracheotomy had been useful, as had also the Schroetter tube. The lesion was to be regarded as a chronic, incurable one, and to a certain degree contagious. The writer deemed it most advisable that the sanitary authorities take action now with view to a prevention of further cases, inasmuch as present cases were few and far between, and the problem presented itself in a comparatively simple form. Quarantine officers should not allow cases of scleroma to land.

Two Cases of Bone Impacted in the Larynx.—Dr. JOHN M. INGERSOLL of Cleveland reported the cases. Case 1 was that of a man with progressive inspiratory dyspnea, leading up to cyanosis and necessitating tracheotomy. The following day examination showed complete abductor paralysis of the larynx, a view below the cords being impossible. Above the cords the organ was inflamed, and two ulcerations were made out. Iodide of potassium was given, but had no effect on the glottic picture. Patient died of septic pneumonia one month later. Autopsy revealed a condition not at all suspected. In addition to the usual septic conditions, a piece of bone irregularly triangular, about 5 cm. long and 2 cm. wide, curved on the flat, was found in a cavity on the posterior wall of the larynx, access thereto being through an ulcer about 2 cm. in diameter. The gullet was intact and its mucosa normal. The bone had evidently fallen into the larynx during a meal and had worked its way through the posterior wall of the larynx into the position in which it was found on autopsy. The man gave no history of any such accident. It had evidently pressed on the recurrent nerves and thus led to the paralysis. A second case was also reported, with similar initial symptoms and which was supposed to be due to syphilis. Tracheotomy was done to relieve the dyspnea. All that could be seen was a grayish, rough surface below the cords. Finally the larynx was split and a piece of bone was found imbedded in the right side of the trachea, just below the larynx. Relief was immediate and complete. In this case also the man had no recollection of ever having swallowed the offending material.

Sarcoma of the Nasopharynx; Treatment by Injections of Adrenalin.—Dr. J. E. RHODES of Chicago re-

ported the case of a married woman of 22 years with the history of a growth commencing in the throat at the age of ten. When seen by the author there was a mass in the nasopharynx completely obstructing the choanæ, severe pain, profuse discharge, and all the features of a chronic sepsis. Palpation showed an attachment to the nasopharyngeal wall and the extension of the mass down nearly to the edge of the soft palate. It was firm though not hard, did not bleed easily, and no ulceration could be made out. Microscopical examination of a fragment showed the tumor to be a spindle-celled sarcoma, highly cellular, with many lymphoid cells. A consideration of all the features in the case led to a decision against operation. Consequently Rhodes determined to inject adrenalin through the nasal channels through a long needle. The symptoms were considerably relieved by this plan of treatment, but the patient died in about two months from exhaustion. The author referred to other cases similarly treated by others and believed that the method deserved a further trial. Reference was also made to the physiological effect of the remedy. Caution was suggested as requisite in this special application of it. It has been found by animal experimentation that arteriosclerosis sometimes follows its prolonged administration.

Dr. C. F. Theisen said that a pathologist in one of the Albany laboratories had produced myocarditis in animals by injections of adrenalin.

Dr. J. Price-Brown had found that adrenalin had an effect in checking the circulation in sarcoma and lessened bleeding. In this disease the characteristic secondary reaction of the remedy seemed to be wanting.

Dr. D. Bryson Delavan did not believe in the theory of the secondary reaction of adrenalin. In his experience it had been entirely wanting. Clinically speaking, the reports of hemorrhage after the use of the remedy had been inconclusive. Hemorrhage occurred in a certain number of cases anyway, and it was not clear to his own mind at least that adrenalin had anything to do with it.

Dr. E. Fletcher Ingals had had excellent results from injections of lactic acid in the case of nasopharyngeal sarcoma. It should be begun in 15 per cent. strength and gradually run up to 35 per cent.

Dr. Norval H. Pierce stated that after injections of adrenalin or its local use on mucous membranes, streptococci and staphylococci were greatly increased in virulency. He would utter a caution in the use of the remedy.

The Removal of Adenoid Vegetations Through the Nasal Passages by a New Method—Dr. Otto T. Freer of Chicago finds objections to the various forms of curette and ring knife now so generally employed, claiming that they do not afford clean and sufficient removal of the offending masses. If the latter are at all tough the blade is apt to slip over them. Moreover, the ramifications of the nasopharyngeal cavity are such that no ring knife or similarly constructed instrument will reach them. Hence Freer prefers to operate through the nasal fossæ and has devised for this purpose a slender forceps with a smoothly rounded beak. It is of the general model originally devised by Ingals for the removal of bone in the nose. At first sight it would seem as if the instrument were too large to pass through the nose, but experience has shown that there is no difficulty in this respect. The author uses chloroform anesthesia combined with cocaine in 10 per cent. solution and has had no difficulty with this combination.

Mouth Breathing.—Dr. William Lincoln of Cleveland read a short paper with this title and illustrated his remarks with lantern slides. He called attention to the fact that many children remained mouth breathers after adenoids and enlarged tonsils had been removed, but the patients have often suffered so great a distortion of the osseous framework of the face, particularly of the upper and lower maxillæ and their arches, that no amount of work by the rhinologist alone will relieve the difficulties from which they suffer. The dentist is the one who can help the sufferer out. Under normal conditions the mouth is closed and the teeth and lips properly apposited by the normal tonicity of the facial and buccal muscles, but when the latter are weakened by altered bone conformation the jaws are closed and held together only by conscious effort. During sleep the jaws drop apart. Sometimes the posterior molars come together in such a way that it is impossible for the incisors to meet. Thus the jaws are locked. The determination of cause and effect in the study of these deformities of the facial bones and lymphoid hypertrophies is not easy. Either condition may be provocative of the other. Adenoids and tonsils may weaken the growing child so that dentition is delayed and teeth decay started and the whole framework of the face and whole body retarded and weakened in texture. Locally it seems probable that if the lymphoid masses are large they may be slight, but constant pressure changes to some extent the correct relation of the upper and lower maxillæ. On the other hand, the normal width and shape of the maxillary arches being disturbed, there must follow septal deformities, turbinal distortion and enlargements, and in consequence encroachments on the lumen of the nares, rendering nasal breathing impossible or very difficult, whereby in turn the nasopharynx suffers and adenoids ensue. The slides shown illustrated the changes in jaw conformation produced by proper dental prosthesis.

Malignant Disease of the Tongue.—Dr. J. H. Bryan of Washington, D. C., discussed two cases. Case 1 was that of a man of 60 years with an indurated ulcer on the right border of the tongue at its posterior third. Strong irritants had given it an inflamed appearance. No glands were found. Diagnosis, malignancy. The patient was operated on by Mr. Butlin of London, who, after doing a preliminary laryngotomy, excised the whole right half of the tongue. Three weeks later a complete dissection was made of all the glands of the neck. Nothing was found in them suggestive of cancer, but the mass removed from the tongue was found to be a squamous-celled carcinoma. Remained well for about seven months, when a swelling appeared in the opposite side of the neck. This was removed, but the next day after the operation the patient developed a hemiplegia and he died of a pneumonia forty-eight hours after operation. Case 2 was that of a man of 70 years who had for some time suffered from dysphagia without apparent cause. Later there developed a mass at the base of the tongue, projecting out of the larynx and suggestive of an exaggerated degree of edema of the epiglottis. There was no pain. The growth bled easily on examination. There was a small glandular enlargement on the left side of the neck at about the bifurcation of the common carotid artery. Examination of a fragment of the growth revealed it to be a surface epithelioma without the formation of pearls. The Kocher operation was performed, it being shown that attachment was to the tongue and not to the epiglottis. Recovery was slow, but uninterrupted. Eight months later the patient was doing fairly well, though troubled somewhat with difficult articulation and accumulation of fluids in the mouth.

Examination of the Throat in Chronic Systemic Infections.—Dr. J. L. Goodale of Boston referred to frequent consultations he had had with orthopedists in regard to the relation of throat conditions to chronic arthritis. The question was constantly arising, did the throat condition account for enlarged cervical glands, and was it the point of entrance for the joint infections? The paper was confined to the consideration of tuberculous lymph nodes and infectious arthritis. Experience has shown that the removal of a septic focus has often relieved the joint symptoms. Ten cases were reported, showing that tuberculous cervical adenitis may exist in association with the

presence of tubercle bacilli in enlarged tonsils with or without visible change in the latter, and is not necessarily affected by tonsillar removal, and, second, that a form of cervical adenitis exists accompanied by distinct enlargement and subacute or chronic inflammation of the tonsils, and disappears after their excision. In the first place it appears reasonable to assume that a penetration of bacilli takes place through the tonsils into the glands, and in the second that an absorption of irritating material has occurred, being generated in the tonsils and conveyed to the glands. Removal of the focus of toxine production is naturally followed by immediate relief. The author then discussed the matter of the modes of penetration of such irritating and infecting material through the tonsils, maintaining that it would be favored by an increase in the size and number of the intercellular spaces of the lacunar epithelium and the retention of crypt contents. Now in regard to chronic arthritis, it may be true that this condition is due to a specific organism, and it is certainly likely, nay more, probable, that such organism is constantly present in the mouth and that certain patients are peculiarly susceptible to it. Given this systematic predisposition, local vulnerability would become of importance in determining an attack. We are therefore compelled to seek for the place of diminished resistance. This may be in the throat, and in all such instances the tonsils should be carefully examined. The arthritic individual predisposed to rheumatic infection finds in certain remedies, diet, etc., means for resisting infection or in controlling bacterial development after entrance thereof. The examination of many cases of infectious arthritis has shown pathological alterations in the tonsils, characterized in general by the retention of lacunar detritus with or without enlargement of the tonsil. Hence if we can eliminate in these joint cases other portals of infection it is logical to thoroughly extirpate the tonsils. We shall thus replace a tissue of diminished resistance by a stout barrier of compact structure without nook or recess to harbor a pathogenic parasite.

Etiology of Hyperkeratosis of the Tonsils.—Dr. George B. Wood of Philadelphia presented a paper on this subject. He took strong issue with those writers who have ascribed the disease to the effect of a specific infection, the leptothrix, declaring that neither this nor any other microorganism stood in such causal relationship. He maintained that it would be as rational to hold the dirt and grime of a miner's hand responsible for the production of the horny layer of the skin as to believe that such a saprophyte as the leptothrix is responsible for what is really a calloused tonsil. There is, it is true, a rather acute infection of the throat in which this organism is probably the exciting cause, but such infection is not limited to the tonsillar tissues and may occur in any portion of the body in which vital resistance has been lowered and to which the organisms have obtained access. True, hyperkeratosis is limited to lymphoid tissue portions of the throat. The true explanation of the condition under discussion is found in the behavior of the epithelium lining the tonsillar crypts. These are dilated and filled with a horny mass which emerges at various points into the epithelium. The latter is in a state of active growth which results in the formation of the keratoid plugs. Other changes may occur, but this change in the epithelium of the crypts is the characteristic pathologic feature of hyperkeratosis. The author is of the opinion that the cryptal epithelium is a primogenial source of lymphocytes. At the bottom of the whole process is a decreased functional activity of the tonsil while a portion of the cryptal epithelium still possesses its physiological tendency toward growth.

Dr. J. H. Bryan opened the discussion on the two last papers on tonsillar conditions. He had had one case in which accumulation in the tonsillar crypts had seemed to stand in a causative relation to arthritis. It was too early to speak positively.

Dr. Thomas Hubbard believed this subject to be a most timely one. We should endeavor to remove tonsils before the child had absorbed enough poison to lead to rheumatic outbreak with consequent valvular cardiac lesions. He had had an interesting series of cases of keratosis occurring in the same family.

Dr. H. L. Swain spoke in commendation of Dr. Goodale's work, which showed, however, that it was not possible always to tell whether tonsils were healthy or not until we had removed and examined them. The statements made in the paper called for a more serious consideration of tonsillar diseases in their relation to systemic infection than we had been accustomed to give.

Dr. Emil Mayer noted that the removal of cheesy contents from tonsillar crypts often cured obstinate cough.

Dr. Goodale in closing the discussion said that the tonsil was only one of a large number of glandular structures, and it would be interesting to know if what was true of it was true also of other lymphoid deposits, such as those in the small bowel, etc. In all suspicious cases we should never omit to carefully examine the tonsils in our search for sources of infection.

Dr. Wood in closing begged to add one or two words on the subject of epithelial metamorphosis. He noted that the thymus, essentially an adenoid structure, had been shown to develop from the epithelial cells forming the original anlage. No leucocytes appeared in the blood until they had occurred in the developing thymus. As the thymus disappeared the tonsils developed and later the solitary lymph follicles of the intestine and the lymphatic tissue of the appendix very possibly carried on this manufacture of leucocytes.

Mixed Tumor of the Soft Palate.—Dr. T. H. Halsted of Syracuse, N. Y., reported the case of a man of 55 years complaining of recent sore throat and hoarseness. He had had similar attacks for fifteen years or more. Examination showed an appearance about the left tonsil suggestive of quinsy with superficial inflammation of all the surrounding parts, but the swollen area was very hard to the feel. The superficial inflammation quickly cleared up, leaving the appearance of an enormously enlarged tonsil buried between the pillars and almost entirely covered by them. The swelling was greatest in the soft palate above the arch and was pushing the posterior pillars backward and largely obstructing the left side of the nasopharynx, extending up to the Eustachian orifice. The mass was of stonelike hardness and had a nodular surface. There were no enlarged glands, cervical swelling, or history of bleeding. A diagnosis of malignant growth was made. Later there was some bleeding from the throat, but no change in appearance. The mass was removed under local anesthesia without difficulty or special incident. The tumor was of oval shape, 7 x 4 x 5 cm. in measurement, and contained several small cysts. Recovery was rapid. At the end of seven months there had been no recurrence. Microscopical diagnosis, a cylindroma evidently originating in connection with the parotid gland (possibly an aberrant portion) or in connection with mucous glands.

Cases of Sarcoma.—Dr. Thomas Hubbard of Toledo presented the reports of two cases. The first was that of sarcoma developing in fibromyxoma of the epitonsillar space. His patient was a man of 40 years, with a mass ovoid in shape and about two and one-half inches in longest diameter, situated just above the left tonsil and in the substance of the soft palate. Nodules gave it an irregular surface and these nodules appeared very vascular. The mass was enucleated under Schleich infiltration anesthesia. No return ten months after operation. Microscopical diagnosis, mixed-celled sarcoma. The second case was sarcoma of the neck following extirpation of the tonsil. Patient was a man of 30 years whose tonsil was removed following enlargement of the cervical glands, the whole picture being suggestive of malignancy. The glands did not subside, but

gave evidence of harboring some septic process, and finally the whole glandular mass was excised. Microscope revealed a small round-celled lymphosarcoma of a compound lymph gland. The patient lived only two months, and before death presented the usual symptoms following involvement of the vagus and its branches.

Officers for the ensuing year were elected as follows: *President,* Dr. A. W. De Roaldes, New Orleans, La.; *First Vice-President,* Dr. G. Hudson Makuen, Philadelphia, Pa.; *Second Vice-President,* Dr. A. B. Thrasher, Cincinnati, Ohio; *Secretary and Treasurer,* Dr. James E. Newcomb, New York City; *Librarian,* Dr. J. H. Bryan, Washington, D. C.; *Member of Council,* Dr. J. W. Gleitsmann, New York City. The meeting for 1907 will be held at Washington, D. C., in connection with the Triennial Congress of that year.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-sixth Annual Meeting, Held at Bedford Springs, September 10, 11, 12, and 13, 1906.

(Special Report to the MEDICAL RECORD).

(*Concluded from page 511.*)

GENERAL SESSION.

Second Day—Wednesday, September 12.

The Thyroids and Parathyroids; Their Relations, Histology, Physiology, and Chemistry.—Dr. ALLEN J. SMITH of Philadelphia presented an elaborate paper upon this subject, saying that the parathyroids and thyroid gland are structurally distinct and are not in any sense interconvertible. That there is some relation in their function was considered probable. The parathyroids were said to be essential to life. The loss of the thyroid, it was stated, was followed by chronic trophic and metabolic disturbances. While the function of the parathyroid strongly suggested its action in an antitoxic manner, there was reason to believe that in case of the thyroid a true metabolic secretion is produced, although he thought it possible that in a limited sense here, too, an antitoxic action was associated. He thought it probable that the active product of the thyroid was one of the iodine-organic compounds which have been isolated from it, probably the thyroglobin of Oswald. He thought there was suggestive evidence that in addition to the indefinite relation believed to exist functionally between the thyroid and parathyroids, there was also a close relation held to the thyroid by the hypophysis cerebri, which possibly may have some degree of compensatory ability.

The Pathology of Diseases of the Thyroid Gland.—Dr. GEORGE P. MÜLLER of Philadelphia, in presenting this paper, stated that, presupposing an acquaintance with the anatomy and histology of the gland, the various affections should be grouped clinically into hypertrophies, tumors, cysts, and inflammations. These main types were said to contain certain subdivisions which were grouped at the end of the paper, but were discussed in the order in which they bear a relation to each other.

Classification of the Diseases of the Thyroid Gland and Therapeutic Uses and Abuses of the Thyroid Gland.—Dr. THEODORE J. ELTERICH of Allegheny classified diseases of the thyroid gland under the captions of congestion, inflammation (thyroiditis), neoplasms, simple hypertrophy (goiter), exophthalmic goiter (Basedow's, Graves', or Parry's disease), cretinism, and myxedema. These several divisions were discussed. Thyroid gland or thyroidin had served more than any other similar substance to establish organotherapy upon a firm basis. The results were most astonishing in myxedema in its various forms, and in cretinism. The indications against the use of thyroid preparations were given as weakness of cardiac action, albuminuria, and glycosuria. Coincident tuberculous disease, or suspicion of grave renal or hepatic disease, should cause hesitation in prescribing the drug.

Symptomatology, Diagnosis, and Medical Treatment of Exophthalmic Goiter.—Dr. ALFRED STENGEL of Philadelphia said that no physician could have seen cases of exophthalmic goiter, or Graves' disease, without having gathered the impression that there are different types classified under one name. Reference was made to the functional element of the secretion of a substance, called thyroglobulin, the overproduction of which was responsible for many of the symptoms which were called Graves' disease. The symptoms were fully considered and a review given of the value of medical treatment, with a consideration of the indication for operative interference.

Surgery of the Thyroid Gland.—Dr. ROBERT G. LECONTE of Philadelphia, owing to the limit of time, elaborated but three points in the surgery of goiter: (1) Mortality was considered, with a view of advising or rejecting operation in an individual case. (2) The indications for operation were considered. (3) The technique of the operation was discussed, including the questions of anesthesia, position, incision, and dissection. In conclusion Dr. LeConte stated his belief, first, that in hopeless cases of malignancy too many radical operations were undertaken where palliative surgery would prolong life and increase the comfort of the patient; second, that in benign tumors of the thyroid, palliative methods were often resorted to when a radical operation should be done, because Graves' disease, or even malignancy, not infrequently was later engrafted.

The Relation Between the Thyroid and the Eye.—Dr. JOHN E. WEEKS of New York, in presenting this paper, drew attention to the fact that diseases of the thyroid and parathyroid were as yet inseparable, and that in considering the symptoms present in the eye due to thyroid disease, disease of the parathyroid must be included. The relation of the thyroid to the eye was considered under a number of headings, a table of which was given, including conditions of the eye due to pressure of thyroid enlargements; to local metastatis of malignant thyroid tumors (very rare); to or associated with absence of thyroid gland; to compensatory enlargement of the hypophysis cerebri; aggravated by or otherwise associated with goiter—Graves' disease, etc.; due to some form of hyperthyresis. Under the head of conditions aggravated by or otherwise associated with goiter, the eye symptoms of Graves' disease were given and fully described. The effects of overdosing with thyroid preparations were also enlarged upon to some extent.

Dr. EDWARD MARTIN, referring to Dr. Stengel's statement of the medical remedies and indication for operative interference, thought the main question was in regard to the length of time medical remedies were to be tried. Surgically, it was known that if the thyroid could be properly removed the symptoms of Graves' disease would disappear. His belief was that when the cases, in spite of any treatment, were progressive, they should be operated upon, and that if operated upon early enough, the operative mortality was almost as low as in operations for appendicitis.

The papers were further discussed by Dr. Samuel D. Risley of Philadelphia and Dr. James I. Johnston of Pittsburg.

The new president, Dr. Isaac C. Gable of York, was introduced, and the announcement was made of Reading as the place of meeting in 1907.

Third Day—Thursday, September 13.

Oration on State Medicine.—Dr. SAMUEL G. DIXON, Health Commissioner of Pennsylvania, delivered this oration. He paid a tribute to the work done by Dr. Benjamin Lee in the State Board of Health and to the members of the medical profession who had stood by the work for twenty years past. He made a plea for vaccination and referred to the fact that a year ago the Department had called attention to a health law which had been on the statute books since 1895, providing that unvaccinated children could not

be admitted to school; and further referred to the accusations that he was breaking up the schools. Much of this prejudice he believed had been overcome. Hundreds of thousands of children had been made immune against smallpox by vaccination. Not only had the Supreme Court of Pennsylvania reaffirmed the law, but the Opinion itself constituted one of the strongest arguments in favor of the vaccination of school children. He outlined the work of the Department in the fight against typhoid fever and in the distribution of diphtheria antitoxin. An earnest effort, he said, would be made to remedy the midwifery evil, and suggested that the Medical Society of the State of Pennsylvania might well lend its influence to such end. To stop the pollution of the waters of the State was also mentioned as an object receiving the attention of the Department of Health.

MEDICAL SECTION.

Third Day—Thursday, September 13.

Etiology and Symptomatology of Stenosis of the Pylorus.—Dr. GEORGE S. DICKINSON of Erie considered briefly the etiology and symptomatology of this condition and cited a few cases illustrative of the causes of the affection and the accompanying symptoms. In the first case cited the condition was attributed to the constant pressure of the stomach against the desk in a man aged fifty years and a bookkeeper.

The Differential Diagnosis and Treatment of Pyloric Stenosis.—Dr. JOHN A. LICHTY of Pittsburg enumerated the symptoms of pyloric stenosis, stating that it should be differentiated from simple atonic dilatation of the stomach, the vomiting of pregnancy, simple hyperchlorhydria, right movable kidney, gastroptosis, gastric neurasthenia, subacute gastric ulcer, hour-glass stomach, certain affections of the pancreas, and cholecystitis with or without local peritonitis. There was, he said, no pathognomonic sign of cancer of the stomach. Reference was made to the discovery by Dr. George Kelling of Dresden of that which he regarded as a reliable hemolytic reaction of the blood serum of cancer cases upon red blood corpuscles of chickens. Treatment in complete cases was regarded as necessarily surgical, pyloroplasty or pylorectomy being the desirable procedure, though the mortality was still too high. For this reason posterior gastroenterostomy was said to be still the operation most frequently employed. In partial stenosis appropriate medical and dietetic treatment was known to produce good results.

Gastroptosis, with Special Reference to Its Treatment.—Dr. JOHN J. GILBRIDE of Philadelphia called attention to the common occurrence of this disease, particularly in women, and to the fact that anomalies in the position of the stomach were more frequently overlooked than recognized. In diagnosis, determination of the lower boundary of the stomach was not considered sufficient, the lesser curvature in a lower position than normal also being essential. The symptomatology was considered. Treatment should be preventive so far as possible. Clothing forcing the abdominal organs downward was discouraged and the bandaging of the abdomen of women during the lying-in period was advised. The treatment proper of dislocation of the stomach was said to be largely mechanical. Diet should be nutritious and easily digestible. The medical treatment was outlined, and it was advised that it should be persistently tried before resorting to surgery. It should be remembered that the patients were often profoundly neurotic. In cases in which the position of the stomach produced a kink at the pylorus, as pointed out by Kussmaul, surgical intervention might be required such as that indicated in cases in which peritonitic adhesions, tumors, etc., existed. A review of the surgical procedures was given, and the most satisfactory method of elevating the stomach was said probably to be the one described and performed by Beyea. The paper was accompanied with illustrative figures.

Hyperchlorhydria and Its Treatment.—Dr. HENRY D. JUMP of Philadelphia enumerated among the causes of hyperchlorhydria overwork, hurry, and excesses in diet. The symptoms were detailed as distress at the epigastrium at the height of digestion and relieved by food, insomnia, constipation, headache, flatulence, apathy, irritability, rheumatism, and increase of hydrochloric acid. In the diagnosis the condition was to be differentiated from ulcer and mild attacks of biliary colic. Treatment consisted in removal of the cause, bland diet, small frequent meals, the use of alkalies and nitrate of silver and belladonna, or the bromides.

Clinical Results from Examination of Feces After Intestinal Test Diet.—Dr. CLEMENT R. JONES of Pittsburg called attention to some of the clinical observations made and the benefits to be derived from the newer methods of examination of fecal matter after the use of the test diet as advised by Adolph Schmidt of Dresden. He thought it a matter of common knowledge that physicians paid far too little attention to the condition, quality, and quantity of the food ingested by the average patient, to say nothing of the examination of the residue that passed from the alimentary canal. The clinical importance of being able to supply to the patient only foods suitable to his gastric and intestinal state proved the value of the examination of fecal matter.

Dr. HENRY D. BEYEA of Philadelphia had never seen a case of gastroptosis with marked symptoms in which any form of mechanical or medical treatment was of value. Since the gastric motor insufficiency seemed to render it impossible for the musculature of the stomach to force the food up toward the pylorus, he thought relief could be secured only by surgical methods. Cases were cited in which he had operated with good results.

Dr. SAMUEL WOLFE of Philadelphia recognized the value of the laboratory investigations of the stomach contents, but thought it good practice to have the patient give a record of what he had eaten, what he had taken in the way of drink, and how many cigars he had smoked.

Dr. RUDOLPH MYERS of Huntingdon had for years been troubled with acidity of the stomach which had been entirely corrected by the use of "soda mints."

Dr. DICKINSON called attention to the possibility of ulcer of the pylorus being diagnosed as cancer, and recalled cases in which this had been done. In two of these recovery ensued upon the institution of appropriate remedies.

Dr. LICHTY called attention to the necessity of removing an ulcer when the abdomen was opened for any cause and an ulcer found in the stomach. If not removed it offered a nidus for infection.

Dr. JUMP took exception to Dr. Gilbride's advocacy of the abdominal binder, stating that it was oftener up under the patient's breast than in the proper position.

Dr. GILBRIDE, in reference to the use of the abdominal binder, said that it was assumed that it was properly applied. He considered it an aid to the abdominal muscles in regaining their tone.

Dr. Jones spoke of the value of the administration of as much milk as could be well taken in cases of hyperchlorhydria. It had been borne out by experiment that milk induced the secretion of but a small amount of gastric juice, especially if taken between meals. As was known, beef acted as a stimulant to the secretion of hydrochloric acid, while the milk caused the secretion of the least amount. He mentioned seven cases of hyperchlorhydria under his care during the past year, a number of which had cleared up by the proper adjustment of glasses, there having been far-sighted astigmatism.

A Peculiar Trophic Affection of the Skin in a Neurotic Subject.—Dr. RUDOLPH MYERS in this paper cited the case of a lady of neurotic tendency, who, after a slight scratch on the ring finger, observed that the skin on the

back of the finger had become dark and sunken in a space three-fourths of an inch long and half an inch wide. New gangrenous points formed until there were fourteen. The attacks recurred every seven days until the patient had had six, the second having occurred after a severe fright. The author regarded the case as an instance of neurotic gangrene.

Dr. Alfred Gordon of Philadelphia called attention to the onset of the condition following excitement which suggested psychic influence. This inference was further confirmed by the results of the treatment employed, that of the electrical current, after which healing rapidly took place. In his judgment the case was one of hysteria. He further called attention to the fact that hysterical patients frequently exhibited superficial tender spots. This could be verified by the fact that while pressure upon the ovary did not give pain, pressure upon the skin at the level of the ovary would often give very severe pain.

Dr. John J. Burke of Pittsburg asked whether it was possible that the woman had produced the lesion by the use of an acid.

Dr. Myers closed the discussion, stating that the gangrenous spots had healed in less than a week after the application of the electricity, and that then a cyst had formed He wondered whether there might not be some condition of Raynaud's disease. The patient had been carefully watched and the possibility of the lesion having been self produced had been eliminated.

Salt-free Treatment of Epilepsy.—Dr. Alfred Gordon of Philadelphia stated the object of his paper to be the application of the knowledge of experimental physiology to clinical studies of epilepsy. It had been shown that sodium chloride played an important rôle in normal metabolism of the body by influencing the elimination of waste products. Applied to epilepsy its presence in the diet increased the severity and the frequency of the seizures. Its withdrawal produced a decidedly beneficial effect upon the duration and the character of the attacks and upon their frequency. From prolonged observation and a systematic study of thirty-seven cases the author concluded that while the removal of the alimentary salt was not a specific for epilepsy, it modified its course, and therefore added a valuable means in treatment.

Dr. Guy Hinsdale of Hot Spring, Va., referred to the retention of chlorides as one of the great disadvantages in cases of renal disease. This fact and the occurrence of convulsions in advanced renal disease formed two points of contact between the two affections. In the employment of mineral waters he would prefer those with as little chloride of sodium as possible and those which tended to dissolve out of the system some of the salts which were known to be injurious.

Dr. Gordon in closing referred to the reported cases of inoperable Jacksonian epilepsy in which dechloridization had given remarkable results.

Symptomatology and Diagnosis of Lobar Pneumonia.—Dr. James I. Johnston of Pittsburg had made an analysis of one hundred cases from the wards in the Mercy Hospital to determine the frequency of the so-called classical symptoms and signs. The initial chill was present in 82 per cent. of the cases; 87 per cent. had pain over the area of lung involved; cough was present in all. Attention was called to the frequency of apical pneumonia in the series, 16 per cent. The cases were all of lobar pneumonia uncomplicated by other diseases.

Certain Complications of Lobar Pneumonia, Considered with Reference to Surgical Interference.—Dr. Philip Y. Eisenberg of Norristown read this paper.

The Treatment of Lobar Pneumonia.—Dr. James M. Anders of Philadelphia said the leading indication in the hygienic management was absolute rest. He advised under feeding, but did not advocate the "therapeutic fast." In the treatment of the toxemia he considered water, six to eight ounces every third hour, the best diuretic. The fresh-air treatment to be effective should be carried out with rigid personal supervision. The importance of maintaining the activity of the sweat glands was shown. When the condition of the circulation cannot be constantly watched he advised the use of cardiac stimulants in small doses almost from the beginning.

Diagnostic Significance of Herpes Simplex in Infectious Diseases.—Dr. Jay F. Schamberg of Philadelphia said it was highly probable that herpes of whatever type was the result of the action of a toxin. Pneumonia, spotted fever, and malaria were said to be the diseases in which herpetogenic toxin developed with a fair degree of constancy. Its frequency in these diseases and its rarity in typhoid fever and other infectious maladies make its appearance a symptom of considerable diagnostic import.

The Relation of the Cardiac Muscle and Valves to Arterial Tension.—Dr. W. M. Stanton of Philadelphia said that the factors concerned in arterial tension were the heart, the arteries, the small vessels under the control of the vasomotor system, and the quality of the blood. The action of these several factors was described. The blood pressure picture was given in cases of aortic regurgitation, aortic stenosis, and other conditions.

Some Aids in Teaching Climatology and Climatotherapy.—Dr. Guy Hinsdale of Hot Springs, Va., suggested the organization of medical journeys, similar to those arranged annually in France, so as to familiarize physicians with climatic stations and sanatoria. A classification of American health resorts on a therapeutic basis was submitted.

Hypertrophic Pulmonary Osteoarthropathy.—Dr. H. R. M. Landis of Philadelphia reported two cases of this rare affection.

The Relation of the Lymph Glands in the Mediastinum to Disease, and Their Value in Early Diagnosis.—Dr. William S. Newcomet of Philadelphia spoke upon the need of signs for the early recognition of chest diseases, and particularly in pulmonary tuberculosis, and said that if the lymphatic glands were properly studied in early cases they would aid materially toward a proper determination of the nature and extent of the disease.

SURGICAL SECTION.

First Day—Tuesday, September 11.

The meeting was called to order by the Chairman, Dr. William L. Estes of South Bethlehem.

Chairman's Address.—Dr. William L. Estes of South Bethlehem, in this address, considered particularly the preventability and cure of syphilis and carcinoma, the first by educating the public in the doctrines of cleanliness and sterilization and the amenability of venereal diseases in the early stages to treatment; the education of the pupils in the higher schools along the lines of sociology, the requirement of aseptic practices in barber shops, etc., and the second by educating the physician to the necessity for prompt diagnosis and early radical removal.

Oration in Neurology.—Dr. Theodore H. Weisenburg of Philadelphia delivered this address, in which he discussed the advances in the surgery of the nervous system considered from the standpoint of the neurologist. He remarked upon the value of surgical measures for the palliative relief of intracranial pressure, even if radical removal was not possible, and urged the necessity for the surgeon to know more of the anatomy of the nervous system.

Cranial Injuries.—Dr. Daniel A. Webb of Scranton, in this paper, considered particularly late cerebellar abscess of traumatic origin, the only treatment for which, he said, was operative (either palliative or curative), and reported a case diagnosed as cerebellar tumor, which autopsy proved to be a deep-seated abscess of the middle lobe.

Fractures of the Base of the Skull, Resulting from Direct Violence Through the Inferior Maxilla.—Dr. Alexander G. Fell of Wilkesbarre, reported a case of compound comminuted fracture between the median line and the left mental foramen, caused by a fall of twenty feet. The patient gradually regained, but there had since developed a slight abscess of the ear.

The Present Status of Cranial Surgery.—Dr. Charles H. Frazier of Philadelphia reviewed the progress of this branch of the science during the last decade, and considered particularly its applicability in epilepsy, hemorrhage of the newborn and childhood, the cranial, fifth, and auditory nerves, and tumors.

Brain Complications Following Mastoiditis.—Dr. Fremont W. Frankhauser of Reading, in this paper, considered meningitis, abscess, thrombus in the internal jugular vein, in the lateral sinus, or in the cavernous sinus, treating particularly of the mode of infection and location of the abscess, and the symptoms, prognosis, and treatment.

An Unusual Case of Trauma of the Head, Exhibiting Symptoms of Astereognosis as the Only Localizing Symptoms.—Drs. John H. W. Rhein and Edward Martin of Philadelphia reported this case.

Impaired Cerebral Development Due to Other Than Cranial Causes, and Its Surgical Treatment.—Dr. Ernest Laplace of Philadelphia considered particularly adenoids, tongue-tie, and phimosis, recommending that they be corrected as promptly as possible, and stating that in the cases which had come under his care this had produced satisfactory results.

Second Day—Wednesday, September 12.

Oration in Gynecology.—Dr. Frank F. Simpson of Pittsburg delivered this oration, in which he reviewed the work that had been done in this field and the progress that had been made.

Surgical Treatment of Chronic Colitis.—Dr. William M. Beach of Pittsburg considered particularly the operation of appendicostomy, and cited as suitable cases for this procedure amebic dysentery, colon adhesions following catarrhal appendicitis, gynecological operations, syphilis and primary tuberculosis of the colon, describing the technique of the operation and the after-treatment.

Dr. George Erety Shoemaker of Philadelphia cited as disadvantages of the operation the establishment of a mucous channel, and the weakening of the abdominal wall.

Dr. J. M. Fisher of Philadelphia believed that the appendix should be opened immediately after attachment.

Dr. J. C. O'Day of Oil City referred to the employment of the procedure in typhoid fever and epilepsy.

Dr. Otto C. Gaub of Pittsburg believed that the operation was not justified in uncomplicated cases of typhoid fever.

A Modification of the Technique of Fixation of Movable Kidney.—Dr. George Erety Shoemaker of Philadelphia read this paper, in which he described in detail the technique of the operation, the chief factor of which was the preservation, instead of the removal of the fatty cushion.

The paper was discussed by Drs. J. C. O'Day of Oil City, Frank F. Simpson of Pittsburg, and John J. Glibride of Philadelphia.

Perineal Prostatectomy—Its Accidents and Complications.—Dr. L. J. Hammond of Philadelphia read this paper. He said he felt that this was both anatomically and clinically the logical route, and cited as indications the impossibility of catheterization, permanent hypertrophy, large amounts of residual urine, frequent and painful micturition, and acute cystitis.

Dr. William L. Rodman favored the same route as the author, except when there was very much enlargement of the middle lobe, projecting into the cavity of the bladder, he preferred the suprapubic.

The paper was further discussed by Dr. John B. Roberts of Philadelphia.

The Value and Safety of Surgical Exploration in the Abdominal Complications of Typhoid Fever.—Dr. John B. Roberts of Philadelphia read this paper. He stated that the only difficulty in these cases was the question of diagnosis, and recommended an exploratory operation in cases of doubt.

The Use of Silk in Tenoplasty—An Experimental Study.—Dr. George P. Muller of Philadelphia reported the experiments made upon ten dogs, in all of which a part of the tendon was removed and replaced by silk suture, the nearest approach to normal being in those cases in which new tendonous tissue had started to form, rather than fibrous tissue.

The Causes of Failure in Tendon Grafting.—Dr. David Silver of Pittsburg attributed these failures to improper selection of cases, and errors in planning and executing the operation, and stated that the operation for its successful performance required great dexterity and accurate technic.

Fractures of the Head of the Radius.—Dr. T. Turner Thomas of Philadelphia read this paper, showing photographs, both of experimental and other fractures, and the difficulty in some instances of detecting the fracture, even by the *x*-ray.

The paper was discussed by Dr. William L. Estes of South Bethlehem, who remarked upon the unusual number of cases of so rare a disease, and closed by the author.

Cleft Palate.—Dr. Henry R. Wharton of Philadelphia stated that the best time to operate was from three to four years, all adenoids, enlarged tonsils, and nasal catarrh having been removed prior to the operation, in order to prevent infection.

This paper was discussed by Drs. John H. Gibbon, John H. Roberts, G. Hudson Makuen, and T. Turner Thomas of Philadelphia.

Third Day—Thursday, September 13.

Address in Surgery.—Dr. Otto C. Gaub of Pittsburg delivered this address, considering particularly the occurrence of hemorrhages in the scalp (dural and intradural), thorax (intrapulmonic and extrapulmonic), and abdomen.

Injuries of the Thoracic Cavity.—Dr. Geo. W. Wagoner of Johnstown read this paper, considering (1) the conditions affecting the walls, and (2) the conditions affecting the abdominal contents. He insisted upon the principles of surgical cleanliness, the removal of destroyed tissue, enlargement of the wound, drainage, disinfection, and rest.

Foreign Bodies in the Larynx.—Dr. Frank Alleman of Lancaster read this paper, in which he considered in detail the etiology, symptomatology and diagnosis (which should be assisted by digital and laryngoscopic examination and the *x*-rays), progress and treatment.

Abscess of the Lung.—Dr. William L. Rodman of Philadelphia read this paper. He stated that, with the exception of cases following influenza, there was usually complex infection. He did not favor exploratory operation, unless immediately to be followed by a radical one, if necessary.

Empyema in Children.—Dr. John H. Jopson of Philadelphia reported a series of cases ranging in age from ten months to thirteen years, and urged prompt diagnosis and careful after-treatment as essential factors.

The Treatment of Pleural Effusions.—Dr. Edward Martin of Philadelphia stated that frank streptococcic infection offered better chances for recovery than latent pleural effusions. He described in detail the method of operation; the puncture in the absence of complications

should be made in the midaxillary line in the sixth interspace.

Surgery of the Thoracic Cavity.—Dr. JOHN C. O'DAY of Oil City considered the various conditions, and the operations therefor, including pneumonectomy, which he believed had a field in suitable cases, and in the treatment of foreign bodies, etc., the *x*-ray.

Dr. JOHN B. ROBERTS of Philadelphia deprecated the practice of inverting the patient in cases of foreign bodies in the respiratory tract, and recommended in cases of broken ribs that the patient be gotten out of bed as promptly as possible, in order to prevent hyperstatic pneumonia and kindred conditions.

Dr. JOHN H. GIBBON advocated rib resection in cases of empyema, even in young children.

Dr. B. FRANKLIN ROYER of Philadelphia reported a case of foreign body in the trachea, which had been sent to the Municipal Hospital, supposed to be a case of diphtheria, the mistake not being discovered until the time of the operation.

These papers were further discussed by Drs. Israel Cleaver of Reading, Theodore B. Appel of Lancaster, Ernest Laplace of Philadelphia, George W. Guthrie of Wilkesbarre, P. Y. Eisenberg of Norristown, Lowell M. Gates of Scranton, and Enfield of Bedford.

The Roentgen Treatment of Tuberculous Glands.—Dr. GEORGE C. JOHNSTON of Pittsburg recommended the application of the *x*-rays as a postoperative measure after complete extirpation of malignant growths, and contrasted this treatment with radical operation.

Surgical Tuberculosis.—Dr. GEORGE W. GUTHRIE of Wilkesbarre stated that in its primary stages tuberculosis was local, and recommended radical removal of the infected gland wherever possible, reporting a number of cases in which early operation had proved effective.

The Clinical Significance of the So-Called Acute Stages of Bone Tuberculosis.—Dr. H. AUGUSTUS WILSON of Philadelphia stated that bone tuberculosis is essentially a chronic insidious process, ad the phenomena heretofore known as acute stages are avoidable sequelæ, and advocated that the conditions be classed where they belong among the complications of the diseased process to be met by appropriate treatment whenever they occur.

These papers were discussed by Drs. John H. Gibbon and Ernest Laplace of Philadelphia, David Silver of Pittsburg, and William L. Estes of South Bethlehem, all of whom recommended early diagnosis and extirpation of the foci of the disease, if possible.

Dr. ISRAEL CLEAVER of Reading reported a case which he had operated on about two years ago with the expectation of finding an ovarian cyst, but which, on opening the peritoneum, was found to be diffused perineal tuberculosis. The operation was formed two years ago, following which the woman made a good recovery, and is now in a healthy condition.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LA MÉLANCOLIE. ÉTUDE MÉDICALE ET PSYCHOLOGIE. By RENE MASSELON. 12mo, 284 pages, flexible muslin. Felix Alcan, Editeur, aPris. Price 4 fr.

PROGRESSIVE MEDICINE. Vol. VIII, No. 2. Edited by HOBART AMORY HARE, M.D., assisted by H. R. M. LANDIS, M.D. 8vo, 368 pages, illustrated paper. Lea Brothers & Co., New York. Price $6.00 per annum.

AMERICAN PRACTICE OF SURGERY. Edited by JOSEPH D. BRYANT, M.D., and ALBERT H. BUCK, M.D. Volume I., 4to, 818 pages, illustrated, muslin. William Wood & Co., New York. Price, muslin, $7.00; brown leather, $8.00, and extra half-levant morocco, $9.00.

DAS PROBLEM DER SYPHILIS UND KRITISCHE BETRACHTUNGEN UBER IHRE BEHANDLUNG. By Prof. Dr. O ROSENBACH Second enlarged edition. 8vo, 164 pages, paper. Verlag von August Hirschwald, Berlin. Price, 3M.60.

TECHNIQUE DU TRAITEMENT DES TUMEURS BLANCHES By Dr. F. CALOT. 8vo, 272 pages, illustrated, paper. Masson et Cie., Editeurs, Paris. Price, 7 fr.

LE SIGNE DE LA MORT RELLE EN L'ABSENCE DU MÉDECIN By Dr. ICARD. 12mo, 292 pages, illustrated, paper. A. Maloine, Editor, Paris. Price, 4 fr.

GYNECOLOGY. (Vol. IV. of the Practical Medicine Series.) Edited by EMILIUS C. DUDLEY, A.M., M.D., and C. VON BACHELLÉ, M.S., M.D. 12mo, 227 pages, illustrated, muslin The Year Book Publishers, Chicago. Price, $1.25.

OBSTETRICS. (Vol. V., The Practical Medicine Series.) Edited by JOSEPH B. DE LEE, A.M., M.D. 12mo, 256 pages, illustrated, muslin. The Year Book Publishers, Chicago. Price, $1.25.

A NON-SURGICAL TREATISE ON DISEASES OF THE PROSTATE GLAND AND ADNEXA. By GEORGE W. OVERALL, A.B., M.D. 12mo, 238 pages, illustrated, muslin. The Rowe Publishing Co.

SPENCER MICROSCOPES AND ACCESSORIES. Microtomes. Bacteriological Apparatus, and Laboratory Supplies. Spencer Lens Company, Buffalo, N. Y.

ELEMENTS OF GENERAL CHEMISTRY, WITH EXPERIMENTS By JOHN H. LONG, M.S., Sc.D. Fourth Edition. 8vo, 443 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.50.

TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D. Seventh Edition. 8vo, 656 pages, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $3.00.

CLINICAL DIAGNOSIS. By CHARLES P. EMERSON, A.B., M.D. 8vo, 641 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

INDEX CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, U. S. ARMY. Second Series, Vol. XI. Mo-Nystrom. 4to, 858 pages, muslin. Government Printing Office, Washington.

REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR ENDING JUNE 30, 1904. Volume II., 8vo, 1,303 pages, muslin. The Government Printing Office, Washington, D. C.

HISTORIC NOTES AND CANADIAN MEDICAL LORE. Lecture Memoranda of the British Medical Association, Toronto, 1906. 16mo, 200 pages, illustrated, leather. Burroughs Wellcome & Co., London, Eng.

CLINICAL BACTERIOLOGY AND HÆMATOLOGY FOR PRACTITIONERS. By W. D'ESTE EMERY, M.D., B.Sc. 8vo, 240 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

HANDBUCH DER SAUERSTOFFTHERAPIE. Herausgegeben von DR. MED. MAX MIQHAELIS. 8vo, 551 pages, illustrated, paper. Verlag von Aug. Hirschwald, Berlin, Germany.

BEITRAGE ZUR KLINIK DER TUBERKULOSE. Herausgegeben von DR. LUDOLPH BRAUER, Band VI., Heftl. 4to, 140 pages, illustrated, paper. A. Stuber's Verlag (Curt Kabitzsch) Wursburg. Preis, M.5.

THE PROPHYLAXIS AND TREATMENT OF INTERNAL DISEASES. By FREDERICK FORCHHEIMER, M.D. 8vo, 652 pages, muslin. D. Appleton & Co., New York City. Price, $5.00 net.

DIET AND DIETETICS. By A. GAUTIER, Edited and Translated by A. J. RICE-OXLEY, M.A., M.D. 8vo, 552 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

DEPARTMENT OF NEUROLOGY, HARVARD MEDICAL SCHOOL. Contributions from the Massachusetts General Hospital, the Boston City Hospital, the Long Island Hospital, and the Neurological Laboratory, Volume I. 8vo, 237 pages, illustrated, paper. The Fort Hill Press, Boston, Mass.

THIRTY-SIXTH ANNUAL REPORT OF THE SECRETARY OF STATE ON THE REGISTRATION OF BIRTHS AND DEATHS, MARRIAGES AND DIVORCES IN MICHIGAN FOR THE YEAR 1902. GEORGE A. PRESCOTT, Sec. of State. 8vo, 212 pages, muslin. Wynkoop, Hallenbeck, Crawford Co., State Printers, Lansing, Mich.

TRANSACTIONS OF THE ASSOCIATION OF HOSPITAL SUPERINTENDENTS, 7th Annual Conference. Volume VII. 8vo. 306 pages, illustrated, paper. Published by the Association.

AIDS TO PHYSIOLOGY. (Students' Aids Series.) By PEYTON T. B. BEALE, F.R.C.S. Eng. 16mo, 239 pages, illustrated, muslin. William Wood & Co., New York. Price $1.25.

AIDS TO CHEMISTRY. (Students' Aids Series.) By T. A. HENRY, D.Sc., Lond. 16mo, 316 pages, muslin. William Wood & Co., New York. Price, $1.25.

AIDS TO SURGERY. (Students' Aids Series.) By JOSEPH CUNNING, M.B., B.S., F.R.C.S. Eng. 16mo, 394 pages, muslin. William Wood & Co., New York. Price, $1.25.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Nebraska.—This State will not grant any license on the reciprocity basis unless the applicant shall have been in active practice in the State by which his license is endorsed for at least one year immediately preceding.

New York.—During the year 1905 622 graduates of medical colleges of this State were examined by the different State boards of the country. Of this number 512 were examined in this State, and 90 in other States. Of the 512 examined in New York ten failed; ten also failed out of the 90 who sought their fortunes in other States. Of the various colleges in the State, Albany, Cornell, the New York Woman's Medical College, Syracuse, and Buffalo passed all their graduates. The College of Physicians and Surgeons of New York had 3.6 per cent. of failures in this State, and 6.7 per cent. of failures in other States. From the Eclectic Medical College all passed in this State, and all failed in other States. Long Island College Hospital had 5.3 per cent. of failures in this State, and 28.6 per cent. of failures in other States. The New York Homeopathic Medical College passed all applicants in this State, and had 33.3 per cent. of failures in other States. The University and Bellevue Hospital Medical College also passed all candidates in this State, and had 6.7 per cent. of failures in other States.

Oregon.—At the July examination there were twenty-four applicants; nineteen of these were successful, and were licensed to practise.

Minnesota.—Eighteen physicians were licensed at the April examination, and sixty-nine at the examination held in June.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 29, 1906:

	Cases	Death
Tuberculosis Pulmonalis	367	151
Diphtheria	137	12
Measles	61	5
Scarlet Fever	41	3
Smallpox	1	—
Varicella	12	—
Typhoid Fever	114	19
Whooping Cough	35	8
Cerebrospinal Meningitis	15	12
Malarial Fever	.....	.....
Totals	783	210

Deaths in Industrial Accidents.—According to the London *Labour Gazette*, out of every 10,000 work people about seven are killed in the year by industrial accidents. In the case of seamen the number killed per 10,000 is about sixty-two.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending September 29, 1906:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Indiana, South Bend	Sept. 16–22	1	..
Kentucky, Lexington	Sept. 8–15	1	..
Louisiana, New Orleans	Sept. 8–15	7	6 Imported.
Ohio, Cincinnati	Sept. 14–21	1	..
Pennsylvania, Altoona	Sept. 15–22	1	1

YELLOW FEVER.

Cuba, Habana	Sept. 27	2	..

THE BATH TREATMENT OF TYPHOID FEVER OF PRIVATE PRACTICE.*

By SIMON BARUCH, M.D.,

NEW YORK

If the choice of title of this paper devolved upon myself it would read "The Bath in Typhoid Fever." It has long been my contention that the expression "treatment of fever" should be relegated to the past, because the modern physician no longer treats the fever, but the patient.

In the management of a case of typhoid fever the chief aim of the well-informed clinician is the enhancement of the patient's resisting capacity to the toxemia which menaces his life. Abundant observation at the bedside made by many physicians in hospital and private practice in various countries has established the fact that the chief lethal element in this disease arises from toxemia, and that in proportion to the intensity of this toxemia is the prognosis of each case; the extent to which the vital organs are affected by the toxic agents set free in the blood by the pathological factors introduced into the system governs the outcome of the case. The damage sustained by the nerve centers which preside over the life-sustaining functions of the organism is the measure by which we are forced to gauge the mildness or severity of a case of typhoid fever.

In the mild cases the action of the toxic material is as obviously upon the nervous system as it is in the more severe types, as is evident in the apathy which finds expression in headache, dullness of intellect, shallow respiration, diminished pulse tension, and depreciated secretory and excretory action. When the system is overwhelmed by these toxic agents the manifestations pointing to involvement of the central nervous system are more pronounced: delirium, coma vigil, subsultus tendinum, cyanosis, elevated temperatures, stupor, cardiac failure indicated by feeble, dicrotic, and rapid pulse; hypostatic congestions, sleeplessness, renal insufficiency with its resulting diminution in the quantity and toxicity of the urine—these point unerringly to a seriously crippled nervous system. This is the broad gateway leading to the dissolution of the vital machinery. To inhibit the latter, we must sustain, refresh, nourish the former; whenever and wherever the nervous system is threatened the medical attendant must be alert and ready to meet the attack. This is the lesson of the bedside as I have learned it from many a hard-fought battle with this, alas but too prevalent, disease. I have learned it sadly from many a defeat, and I have learned it gladly from many a victory.

How much the bath has contributed to my victories during the past twenty-five years of practice and how much previous unfamiliarity with this remedial agent has led to defeat is so deeply engraved upon my mind that I would be derelict to duty as a physician were I to permit any occasion for expression of the plain and incontrovertible experience it has been my privilege to gather in hospital and private practice to pass. That I was long a sceptic on the value of the bath in typhoid fever may not seem a correct statement of fact to those who have so often heard me in these halls as a persistent and ardent advocate. My conversion was not sudden, but an evolution of bedside observation. Well do I remember a note from the lamented Brand of Stettin in which he twitted me with the statement I had made in the Academy of Medicine that "the Brand method may be adapted to the robust German soldier, but that the American would not be a favorable subject for so heroic a measure."

It is an erroneous habit of the physician to trust entirely to experience in accepting a therapeutic agent. Hippocrates himself has said "Art is long, life is short, judgment difficult, experience fallacious." The dark ages of medicine were the times when experience alone was the guide to practice; the brilliant achievements of modern medicine are coeval with the rise and progress of enlightened pathology, and a therapeusis based upon the latter and upon a correct rationale of the action of the remedies applied.

So long as the principal testimony in favor of the bath was derived from the statements of the empirics who boasted of their experience with water, it failed to appeal to my judgment. When, however, Brand demonstrated that the action of the bath in typhoid fever was based upon a rationale derived from its physiological action as a thermic and mechanical irritant—a rationale first insisted upon by Winternitz and his school—and when this clear rationale was substantiated by large statistical material, the evidence became overwhelming that the bath constituted a most important therapeutic agent in this disease.

Although the cold bath had long been applied in fevers with more or less success (usually the latter), it remained for Ernst Brand to insist that the cold bath was not valuable because of its antithermic effect, but by reason of its action as a sustaining agent of the crippled nervous system, and that when properly executed and *applied early* the bath was a prophylactic against all the lethal conditions which existed in typhoid fever. It was Brand who insisted, despite strongest opposition and scepticism, that treating the lethal complications arising in this disease symptomatically was a fatal error, to which the enormous mortality of the disease may be traced quite often. It was Brand who taught the fatal fallacy of treating temperature elevation by the bath or otherwise: it was he who taught us the inestimable value of friction during the bath. For these and

*Read by invitation at a meeting of the Medical Society of the County of New York, September 21, 1906.

other reasons upon which the enormous beneficence of the Brand method and its superiority over all bath methods is based, for the persistence, earnestness, courage, love of his kind, for the polemic ability and logical brilliancy with which he battled for his method for thirty years, Ernst Brand is entitled to be regarded as one of the benefactors of mankind.

While I still regard this well-thought-out and practically-demonstrated method as the ideal treatment of a large proportion of cases of typhoid fever in private practice, and while I still believe that this method is more applicable in private than in hospital practice, by reason of the latter usually being admitted too late to obtain its chief advantage—early application—I am free to confess that there are very many cases in which a strict execution of this systematic bath method is impossible or not indicated. If the principles of the method are understood and followed, any method of cold bathing may be usefully applied. What are these principles?

It is a trite and long-accepted fact in physiology that cold is an irritant to the sensory terminals in the skin, and that, like all irritants, when applied in mild form, it stimulates these sensory terminals, and when applied in more intense form it depresses, and that the stimulation or depression evoked by cold is conveyed to the central nervous system, and thence reflected upon the organs which derive their functionating capacity from the latter. A brief application of cold water to the skin acts as a stimulant; a prolonged application acts as a depressant; both effects being in exact proportion to the degree of cold and to the extent of surface attacked. The truth of this physiological principle, and the correctness of the practice based upon it, is daily exemplified and clearly demonstrated in the familiar management of the still-born infant. In a mild case simple sprinkling with moderately cold water suffices to arouse the flagging vitality; in more pronounced cases a dip into cold water restores the almost inanimate creature; and, if these measures are inadequate, we resort to still colder water, or we render the skin more sensitive to the latter by alternate dipping into water of a high and low temperature. The resultant effect of these applications is one of the first lessons the medical student learns in physiology and therapeutics, and yet *mirabile dictu* their self-evident application in the management of the typhoid fever patient is of comparatively recent date, and still calls for frequent insistence. For twenty years have I emphasized that these trite physiological principles are the basis, and form the rationale of all water treatment in all diseases in which it is indicated. It is not men, nor is it methods, that I advocate, but principles, accepted physiological principles. Applied to the management of the disease under consideration to-night, what effects are evoked by the cold bath? Is so heroic a measure expedient or necessary when milder measures have proved effective? These are important questions, and they are answered by strict application of the principles involved and briefly recited above.

Granted that they are correct, and that the reflex stimulating effects of cold water elicited in the still-born infant and its similar effect in syncope are undeniable as they are in that other and essentially different toxic depression of the nervous system encountered in opium poisoning, it cannot be difficult to appreciate how the stimulating and sustaining effect of properly graded or dosed baths, or other water procedures, arouse the blunted nerve centers in typhoid fever, how the whole machinery of the depreciated organism is thereby revived, how the apathetic countenance brightens, the eye resumes its lost luster, how the breathing is deepened and the blood thus better oxygenated, how the heart, enfeebled by the toxic depression of its nerve supply, responds under the refreshing impulses, and how the secretions and excretions are thus revived.

There are other equally important results arising from the local thermic stimulation of the cutaneous arterioles, enhanced as they are by the mechanical stimulation of friction, which must never be omitted in any cold application.

It has been shown by several laboratory experiments that the Eberth bacillus not only exerts its baneful depressing influence upon the central nervous system, but that it manifests a somewhat specific depreciating and enfeebling influence upon the peripheral arterioles. To the latter may be ascribed that relaxed and sluggish condition of the cutaneous arterioles which is manifested in the deadly pallor of the skin of the trunk, in the feeble and dicrotic and compressible pulse, in the hypostatic congestions, ulcerations of Peyer's glands, etc. These are the result of more or less cardiac inadequacy; the resistance at the periphery being diminished, the vasomotor system is crippled, thus suffering at both ends. The heart is called upon to compensate for this failure at the periphery by increased action; the pulse is accelerated, but the arteries do not fill, as is but too evident in the compressibility of the radial artery.

In mild cases the self-regulating machinery of the organism readjusts itself; in severe cases heart failure, with all its dire effects, ensues; stimulants fail because the nerve centers have lost their responsive capacity, and the physician stands appalled in this trying emergency; too often is he helpless to rescue the patient who, perhaps, in the earlier stages has been promising of better results.

In such emergencies I have long ago asked myself the question, "Cannot these fatal heart failures be prevented?" Brand has answered this question in the affirmative. The ideal cold bath devised by him is a preventive measure, and not a symptomatic one. Cold baths must not be regarded as cooling procedures—a fallacy arising from regarding hyperpyrexia a prominent cause of death in typhoid fever. The latter has been proven to be due to the toxemia. *Cold baths prevent lethal complications by reason of their sustaining effects upon the central nervous and circulatory systems.* Let this truth become the ruling idea in typhoid fever, and let the accepted truth that therapeutic results are in proportion to the dosage of the remedial agent be added, and the aggregate outcome of this much-to-be-desired consummation will be a rational application and consequent cessation of disputes about modes of bathing. Whether the ideal Brand bath is to be adopted in the concrete case, or some milder method, whether so-called sponging, ablution, affusion, compresses, packs, whole baths or half baths, brief or prolonged, higher or lower temperatures are to be applied, must depend upon the individual case.

There must be reaction, that is, refreshment, and not depression, following each application; the sum total of these must inure to the sustenance of the depreciated nerve centers, and they must be adapted to the case with the same intelligence as are diet and medication. By food, nutrition is sustained to prevent starvation; by baths, nerve force must be sus-

tained to prevent exhaustion. Both are prophylactic measures to enhance the patient's resisting capacity. The strict Brand method has proven its efficiency by the largest and most reliable statistics extant in medicine, and it is based upon a correct rationale; for this reason it became the leading treatment in hospitals. It has not remained popular, because its splendid reduction of mortality was obtained first in military hospitals, in which its most important elements—early application and systematic execution—were not difficult. When this method was applied on a large scale in civil hospitals, the same results were not attained, because in the latter typhoid cases are usually admitted after the fifth day, oftener after the first or second week. Nevertheless, the cold bath has proven an efficient aid, changing the mortality statistics and affording such comfort to the physician, who modified it in accordance with the stage of the disease, which, as is well known, changes the responsive capacity of the patient. This is the reason why the Brand bath has fallen into desuetude in Germany. Its strict application is not adapted to the latter stages of the disease, unless it has been used with good results in the early stages. And this is the reason why this bath is better adapted for private than for civil hospital practice.

If the principles here enunciated regarding the physiological action of the cold bath, and its prophylactic nerve-refreshing and heart-sustaining effect are borne in mind by the physician, he will begin with mild measures—ablutions, affusions, baths of 90° F. reduced every four hours one or more degrees, until the temperature of the Brand bath, 70° F., is reached. And if the bath is administered with friction for fifteen minutes, and repeated only during the waking hours every four hours; in fact, if the rules laid down in works on Hydrotherapy were studied and followed as are the rules of other therapeutic agents, there would remain no reason for disputing the practical results of the bath treatment in typhoid fever.

THE PATHOGENESIS AND THERAPEUTICS OF CANCER.

By ROBERT BELL, M.D., F.F.P.S.,
LONDON, ENGLAND.
LATE SENIOR PHYSICIAN TO THE GLASGOW HOSPITAL FOR WOMEN

The study of cancer, as we know, is one of growing importance, and to which it is impossible to devote too much careful attention. In the endeavor to do justice to so momentous a subject, it is incumbent upon us to make ourselves intimately acquainted, not only with its etiology, but with those diagnostic features which differentiate it from affections presenting a somewhat similar appearance to the eye and touch. Now this is not always quite so simple a matter as some may imagine, and more especially in the initial stage of the disease. For example, several instances have come under my observation during the past few months where scirrhus of the mamma has been *stated to exist—diagnosed* would be an improper term—and where immediate operation had been urged by well known surgeons, but, on further examination, the tumor proved to be a simple adenoma, and readily yielded to a much more rational line of treatment. It is not always wise, therefore, to assume that, because a tumor appears in an organ which is known to be susceptible to cancer, it is necessarily of a malignant type. There may be a possibility certainly—though the probability is remote—that, later on, it may develop malignancy. It is, I am sure, because this mistake in diagnosis is so frequently made that we hear occasionally of nonrecurrence after operation. On the other hand, when the diagnosis has proved to have been correct, and the tumor to be cancer, recurrence is inevitable, and, I venture to add, it will be difficult to contest this assertion, for the cogent reason that it is a fact. How can it be otherwise, when we know that in the majority of instances an injury is the *exciting* cause of cancer—the predisposing cause being so far latent in each instance—and when we realize that a much greater injury is inflicted by the mutilation of the parts, which is necessarily the accompaniment of an operation of such magnitude? Is it not very suggestive that the recurrence invariably manifests its presence primarily in the weakest structure, viz., the cicatrix, and thence radiates to the enfeebled tissues in its immediate neighborhood? Having admittedly such ample evidence of the mischief the knife inflicts in malignant disease, and knowing that in no instance can it hold out more than the remotest prospect of conferring any lasting benefit, but on the contrary shortens life and aggravates suffering, how can any right-thinking man deceive both himself and his patients by having recourse to it? No; our line of duty points to our employing unremitting effort to discover a more rational method of dealing with this formidable disease. In our endeavor, then, to attain this desired end, it is essential in the first instance that we devote the most careful study to its natural history.

Doubtless, without fear of contradiction, we may now assume that cancer is not due to a parasite of one kind or another, as so many, only theoretically however, have persistently maintained. This theory, I have no hesitation in averring, has been exploded by authorities whose conclusions are based upon much more substantial foundations than the advocates of the microbic or parasitic theories are entitled to build upon. We, therefore, are left no resource but to search for an explanation of the incidence of cancer in hitherto untrodden fields of investigation. In this we must of necessity be guided to a great extent by noting the pathogenic conditions which, as far as we can judge, lead up to its development. We shall require also carefully to observe those surroundings which we know obtain where the predisposition to cancer is absent. We are aware, for instance, of the very striking circumstance that it is unduly prevalent in civilized nations, and still more so in proportion to the extent that luxury and self-indulgence prevails. Metchnikoff says that "the refinements of civilization have made the demands on man's animal frame too heavy to meet, and to this we may trace at least most of the ills man is heir to." Among savages cancer has been proved to be nonexistent. We cannot, therefore, but admit that our mode of life exercises a considerable influence in its causation. Moreover, in wild animals it is unknown, yet it would appear to assert its presence in animals, and even in fish, whose lives are spent in the neighborhood or under the influence of man. That the tumors in these instances are identical with cancer in the human subject I am inclined to doubt, and for this reason, that in store-fed cattle for example, the disease designated as cancer—whatever be its nature—does not seem to affect the nutrition of the animal, whereas in man it always does so very markedly. I have known cases where attenuation was so rapid that the patients lost flesh at an alarming rate. One case is present to my mind where the loss of weight was three stones (42 pounds) in as many months. Again, we should not lose sight of the fact that the growths which develop in animals occur only when

they are overfed, and upon material which differs substantially from their natural food. This applies equally to fishes in a river or estuary into which all sorts of extraneous matter is emptied, much of which is consumed by the fish. This being foreign to their normal requirements, and therefore unsuitable to them as healthy nutriment, and moreover being superabundant, will eventually act detrimentally upon their organs of digestion and assimilation, thus upsetting their physiological equilibrium, and so give rise to abnormal cell metabolism.

We seem impelled, therefore, to the inference at all events, if not to the conclusion, that the mode of life plays a most important rôle in the production of cancer. That it is a disease quite independent of any specific agent from without is beyond dispute. We have no choice, therefore, but to search for its causation within the body itself, and endeavor to ascertain in what consists the influences which so interfere with normal cell metabolism as to enable certain cells to assume a character altogether at variance with that of the normally conducted cells from which they sprung, and of which they are the direct descendants. With this change they would appear to have disassociated themselves and severed their allegiance to those physiological laws which regulate the metabolic phenomena characteristic of normal cell life. Ultimately they deevlop a morbid influence which is inimical to the integrity of the tissue from which they emanate, and by which they are encompassed.

Having separated themselves from those laws which control and govern healthy metabolism, they eventually become a law unto themselves, and establish a potency quite foreign to that of healthy cells. Their instincts, it would appear, have undergone a complete metamorphosis, for, in place of deriving nourishment from a normal source, they commence to prey upon their neighbors, and, devouring these, replace them by their own voracious progeny, which continue to increase in numbers at an alarming rate, involving successive areas, and, by the lymphatic channels, extend their sphere of influence, establishing new centers of disease in neighboring glands and distant tissues. Meanwhile, the vile juices, which these cannibal cells throw off, contaminate the blood with their poison, when the conquest becomes complete.

Now arises the question: What are the predisposing causes which, if not suppressed or overcome in the initial stage of their activity, will eventually culminate in a calamity? Can they be restrained, and can they be conquered? I have no hesitation in replying in the affirmative to both questions. It is needless for me to enter fully into the pathogenesis and pathology of cancer at this time of day, seeing these subjects have been amply dealt with in my book, published three and a half years ago, but I will just touch upon one or two points of interest, which I am convinced bear to an important extent upon the pathogenesis of the disease.

The organs of the human body are capable of accomplishing only a limited amount of work, and though more elastic than an ordinary machine, yet, when persistently overtaxed, they are liable eventually to succumb; and especially will this prove to be the case if they are handicapped by certain important hygienic laws being continuously ignored; which laws, when in force, act as safety valves. If, for example, an individual—and there are many such—will persist in indulging too freely at the table, thereby habitually burdening the stomach with more work than it can efficiently and advantageously perform, the functional activity of the organ will, as a matter of course, speedily be reduced to a dangerous extent, when a larger proportion of the ingested, but not digested food, will find its way into the colon in a decomposed and highly offensive condition. If the effete matter is discharged without delay, possibly little mischief beyond a slight amount of discomfort may result. On the other hand, however, if the colon and rectum, from lack of expulsive power—and this is, as a rule, due to neglect—should be so tolerant of this fetid material as to permit of its retention for a longer period than is desirable, then absorption of toxic material is certain to take place, resulting in contamination of the blood stream, and deterioration of its essential constituents. The consequence is that every physiological sequence is liable to occur in an erratic manner, and the various organs are rendered incapable of remaining true to their vital relationship with those organs and tissues which are subordinate to them. Especially does this condition of the blood seem to act prejudicially upon the thyroid gland, which, we know, in its active condition exercises a most important influence upon cell metabolism. Now, if this organ for a lengthened period continues to receive its blood supply from a vitiated source, it not only loses its functional activity, but gradually undergoes an atrophic change, and consequently is liable to become permanently disabled; and it has been demonstrated that atrophy, or at least a diminution in size of this gland, is, as a rule, coincident with the advent of cancer.

Now, from my point of view, if a person is a gross feeder, and more so if he indulges to excess in animal food, and if there is superadded a constipated habit, which has such a pernicious effect upon the thyroid gland, we may conclude there are present the three most important factors whose combined influence is sufficient to provoke a tendency to the development of cancer. "Recent research has shown that the bacteria of the human intestine increases at the rate of 128,000,000,000,000 each day, the greater part being found in the large intestine." Can we be surprised, then, that, with such a poison factory within him, one's blood will become sadly vitiated and the normal processes of the economy be injuriously affected if constipation is coexistent? The longer this offensive material is retained the more obnoxious it will become, and its toxic effect increased pro rata.

Now it has been demonstrated that the thyroid gland exerts an inhibitive influence upon this toxic matter when absorbed, so it is not difficult to comprehend how very serious a menace to health constipation will become if the vital force of this gland is reduced. The first principle, then, we must inculcate, when the treatment of cancer is under consideration, is to insist upon a *complete* daily evacuation of the bowels. Second, the diet must be restricted to the actual requirements of the body and the capabilities of the digestive organs; butcher meat must be barred and a vegetarian diet be relied upon to a large extent. Thirdly, the defective action of the thyroid gland must be supplemented by the administration of the gland of healthy animals, or the active principle of the gland, at least three times daily. Fourthly, as saccharomyces are invariably present in the blood in cancer subjects, and as these act injuriously in inducing fermentive changes upon the absorbed enterotoxins, they should be destroyed by giving ten to fifteen grains of salicylate of sodium thrice daily along with a thyroid preparation.

If the uterus is the seat of disease, the parts should be kept scrupulously clean by douching, after which a tampon, saturated in a 10 per cent. solution

of ichthyol in glycerin, should be introduced, and renewed every twenty-four hours for a week or two, and afterwards at longer intervals.

In scirrhus of the mamma, I have seen considerable assistance derived by the inunction of an ointment of cocaine and morphine muriate, each 10 grains in half an ounce each of lanolin and vaselin. A piece about the size of a pea should be rubbed well in over the tumor and surrounding skin night and morning.

[illegible]

THE OPERATIVE TREATMENT OF ACUTE GONORRHEAL EPIDIDYMITIS.

By FRANCIS R. HAGNER, M.D.,

[illegible]

MEMBER OF THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS, AND THE AMERICAN [illegible] ASSOCIATION, CONSULTING GENITO-URINARY SURGEON GARFIELD MEMORIAL HOSPITAL; PROFESSOR OF GENITOURINARY SURGERY, GEORGE WASHINGTON UNIVERSITY.

When the earlier cases, here reported, were operated upon, I knew that puncture of the epididymis and tunica albuginea had been practised for the relief of pain in these conditions, but was unaware of the performance of any open operation for this complication of gonorrhea. Upon investigating the literature of the subject, however, I found that incision of the tunica albuginea had been practised some fifty years ago for orchitis. Mr. Smith[1] states that Pirogoff, in 1852, punctured the testicle for orchitis. (I may say here that most of the older writers seem to make no distinction between orchitis and epididymitis.) Mons. Vidal de Cassis was the first to make an incision through the tunica albuginea and received the sanction of Mons. Ricord. In 1863 H. Smith reported, in the *Lancet*, that he had performed the operation, resorting to it because of an erroneous diagnosis of abscess of the testicle, the result being a discharge of blood and serum, but no pus, with complete relief of pain, which led him to practise it on the incredible number of 1,000 cases, reserving it only for the severer forms. This statement led to a ludicrous discussion between Mr. Smith and Mr. Holmes, the latter taking the position adverse to operating, all of which appears in the *Lancet* of 1864. Watson and John Hunter seem to have been the first to regard the swelling due to gonorrhea as affecting both the testicle and the epididymis. And the former cited the anatomical analogy between the eye and the testicle as to its firm, fibrous, capsular covering. As iridectomy and puncture of the sclerotic coat was a well-recognized therapeutic measure, they concluded that puncture of the tunica albuginea was indicated. Macnamara[2,3] bears out Watson in this analogy by citing the great relief afforded glaucoma by puncture.

Puncture of the tunica vaginalis was recommended by Mr. Spencer Watson in 1867. In an experience of twenty cases, particularly when effusion was present, it seemed to give as much or more relief than puncture of the tunica albuginea. It is apparent after a careful examination of the literature, that it has been only in comparatively recent years that the involvement of the epididymis was recognized of more moment in gonorrheal infection than the involvement of the testicle.

Dr. W. T. Belfield[4] published a very interesting article, under the title of "Pus Tubes in the Male and Their Treatment." I will quote rather freely from his paper, as his experience and mine coincide very closely in a great many ways. He states that it is the general belief that pus rarely forms in gonorrheal epididymitis, but it is his opinion, and one in which I fully concur, that in a considerable proportion of the cases, where the tunica vaginalis contains fluid, and an edema of the skin appears, pus is present in the epididymis. In fact, in one of my cases, where there was no edema of the skin and only a slight hydrocele, pus, in which were numerous gonococci, was found after puncture of the epididymis. He regards the condition as quite analogous to pyosalpinx and recommends a similar treatment—surgical in character—making a good free incision into the globus minor to permit of free evacuation of pus and to allow drainage.

Baerman,[5] in the pathological study of twenty-eight cases, deduced some valuable conclusions, which are undoubtedly correct and which ought to throw much light on the future care of these cases. They are: (1) In a considerable proportion of cases of epididymis, abscesses are formed in the epididymis. (2) Suppuration is regularly followed by the appearance of hydrocele. (In my experience hydrocele has formed when no pus was demonstrable.) (3) Gonococci are found in foci in the epididymis years after the urethral infection occurred. (4) Early puncture is advised to save the canal from occlusion. (5) The hydrocele should be punctured to improve the circulation. (6) Incision and drainage of the infected epididymis should be more frequently practised.

Since becoming interested in this work I have endeavored to secure a testicle in a state of acute gonorrheal inflammation, but, to my great disappointment, have failed, and therefore I will have to rely on the excellent pathological reports of Monod and Terrillon in their book entitled "Traité des Maladies du Testicule et ses Annexes." These observers have deduced the following facts by their exhaustive experiments and pathological studies: (1) "In gonorrheal diseases of the testicle, the epididymis only is involved." From my limited experience this appears to be true, as there seemed to be no change in the testicle proper in any of my cases, and in one very severe case I punctured the tunica albuginea and observed an apparently healthy condition of the testicle.

(2) "There is a marked dilatation of all the tubes of the epididymis, which they believe to be due to the pressure caused by the infiltration of the inflammatory exudate into the connective tissue surrounding the tubules, resulting in more pressure at one point than another, and hence the obstruction produced causes a backing up of degenerated epithelial cells, pus, refractive granular material and spermatozoids." If Monod and Terrillon be correct in stating that the infiltration in the connective tissue of the epididymis causes the obstruction of the tubules in severe cases of epididymitis, then anything that will prevent or lessen this infiltrate is rational and justifiable. Even in the cases where pus is not found, the infiltration is certainly relieved by the puncture.

(3) "Such obstructions have been known to lead to a most distressing complication, namely, degeneration of the seminiferous tubules with resulting atrophy of the testicle." Therefore any operation that will rapidly relieve the tension in the early stage is a most important step in the right direction.

Experiments made by Monod, Terrillon, and Kocher to produce artificially the macroscopical picture of gonorrheal epididymitis, tend to show that the enlargement of the epididymis is due to the inflammatory exudate into the cellular tissue surrounding the tubules rather than to the changes which occur in the tubules themselves. After having dissected off the connective fibrous tunic from the cord and having made an opening at its upper

and anterior border, they fixed a cannula into the cellular tissue. Through the cannula they injected a weak solution of gentian violet. When the fibrous tunic had been sufficiently filled they saw that the induration characteristic of this special form was reproduced, and resembled an increase in size of the epididymis.

I have recently duplicated this experiment, precisely as described above, and present herewith the results by means of two drawings made from photographs.

Fig. 1.

Fig. 2.

Figure 1 shows the testicle, before injection, with the tunica vaginalis dissected off. The second illustration shows the same testicle after injection with a solution of gentian violet, the needle having been inserted through the fibrous covering of the epididymis in the regions of the globus major and minor. The encroachment of the epididymis upon the testicle is shown, and the picture certainly resembles the condition seen in a mild case of epididymitis. Of course, in a true epididymitis the infiltration is much greater than can be produced artificially.

I realize thoroughly that in epididymitis most cases will recover with only medical treatment, but judging from my own cases, limited in number, I do not believe that the severe cases will recover as rapidly or with as little apparent anatomical disorganization, when medical treatment alone is employed. Feeling this to be true, I have operated on only the severe cases coming under my care. Although my confidence in the operation is great, I do not feel I have as yet had sufficient experience to recommend operation in every case, but I believe there will be an increasing proportion to be treated surgically in the future.

The analogy between the two affections and the good results secured by opening and irrigating gonorrheal joints, suggested to me the open method of treating gonorrheal epididymitis. The operation employed by me is as follows:

The patient is prepared as for a major operation and then anesthetized. Cocaine is not practicable because of the pain occasioned in handling the parts after the initial steps. At the juncture of the swollen epididymis and testicle an incision 6 to 10 cm. in length, depending upon the amount of enlargement, is made through the scrotum down to the tunica vaginalis, which is opened at the juncture of the epididymis and testicle. After the serous membrane is opened all the fluid is evacuated and the enlarged epididymis examined through the wound. The testicle with its adnexa is delivered from the tunica vaginalis and enveloped with warm towels. The epididymis is then examined and multiple punctures made through its fibrous covering with a tenotome, especially over those portions where the enlargement and thickening is greatest. The knife is carried deep enough to penetrate the thickened fibrous capsule and enter the infiltrated connective tissue. When the knife is through the thickened covering of the epididymis a very marked lessening of resistance will be felt. If pus be seen to escape from any of the punctures, the opening is enlarged and a small probe inserted in the direction from which the pus flows. By this method I believe there is less danger of injuring the tubes of the epididymis than by cutting with a knife. After the probe is passed in, pus will be evacuated by light massage in the region of the abscess and a fine-pointed syringe is used to wash out the cavity with 1 to 1,000 bichloride of mercury, followed by physiological salt solution. The testicle is then restored to its normal position, and in every case the tunica vaginalis is thoroughly washed with 1 to 1,000 bichloride, followed by normal salt solution. The incision of the tunica vaginalis is lightly closed with a running catgut suture, a cigarette drain of gauze is then applied over the incision, the skin being brought together with a subcutaneous silver wire suture, the cigarette drain passing out at the lower angle of the wound. Silver foil and a sterile dressing are now applied and the part supported by a wide T bandage.

In every case in which I have operated fluid has been present in the tunica vaginalis, varying in amount from a few drams to two ounces; the larger the swelling the greater the amount of fluid. This fluid resembles that seen in gonorrheal joints, in that it is usually slightly blood stained and contains a varying amount of fibrous material in which are entangled a few leucocytes. The parietal layer of the tunica vaginalis is congested and that portion of the tunic covering the epididymis is intensely congested and seems to be the seat of small punctiform hemorrhages. In one case the whole of the body and globus minor was covered by a false membrane, almost like that of diphtheria, which left a bleeding surface on removal. This membrane is composed of fibrin, a few leucocytes, and cell detritus; no gonococci were demonstrable in the membrane, but were found in the pus collected by puncture of the epididymis. I believe this description is identical with that in gonorrheal inflammation of synovial membranes. Of the six cases operated on, in three no pus could be demonstrated, but in the tunica vaginalis of one of these gonococci were present. In three pus was obtained and in two of the latter cases gonococci were found.

On palpation the epididymis is very much thickened, being more marked in the region of the globus minor. Here it is of stony hardness and, on puncture, blood of almost tarry appearance will exude. The body is infiltrated in the same manner but not to the same degree. The globus major, in the cases operated on, appeared to be the most involved portion, next to the globus minor, and it is in this latter locality that I have found pus containing gonococci in two of my cases. In one case there was so much infiltration of the epididymis that the tunica vaginalis was incised at its juncture with the epididymis. The skin and subcutaneous tissue were dissected off the posterior aspect of the epididymis and punctures were made in this region with the expected exudation of blood and pus.

The relief seems to be just as great whether or not pus be obtained, and these results are, I believe, explained by the relief of tension obtained by the multiple punctures of the epididymis, the evacua-

tion of the fluid from the tunica vaginalis, and the drainage referred to in the operation. As has been heretofore stated, the cases operated upon have been of a severe type, with great pain, tenderness, and swelling; one of them, on admission to the hospital, was taking one-half grain of morphia every three or four hours with very little relief. Following the operation, every case was marked by instantaneous and permanent relief from pain, no anodyne being required. The second day after the operation the cigarette drain is removed and the wound redressed, when there is usually noted a small amount of ooze on the dressings. The drainage continues for from four to six days and in a week the wound is healed. The patients have, in every instance but one, been up and walking around, free from pain, by the seventh day. The remarkable feature is the rapidity with which the induration, not only of the epididymis but of the cord, disappears, it being much more rapid than by any other method known to me. The fall of the leucocyte count is rather interesting, the most marked being from 18,600 to 9,000 in forty-eight hours. Along with the decrease in leucocytosis is a parallel fall in the temperature curve and pulse, the temperature reaching normal within thirty-six hours and remaining there, or with a very slight fluctuation, not over half a degree. There have been no cases of infection following the operation, nor have there been any cases of recurrence, atrophy of the testicle, or other distressing sequelæ. I have operated on six cases by this method, and while realizing perfectly that no very valuable conclusions can be drawn from such a small series, I believe that the results warrant a further trial of operative procedure along this line, and that the facts stated fairly justify the following deductions:

1. According to the known pathology, it is a rational procedure.
2. If care be exercised, the danger to the patient is slight.
3. The infiltration of the epididymis disappears more rapidly under the operative treatment than under any other.
4. The danger of permanent injury to the testicle and epididymis is lessened.
5. The patients are absolutely relieved of pain on recovery from the anesthetic.
6. The systemic symptoms are promptly relieved.
7. Medicinal treatment will usually be followed only by relative relief and perhaps not by a permanent cure, because the infecting agent remains. And therefore the most rational way to do away with this is by incision, irrigation, and drainage.

REPORT OF CASES.

Case I.—F. V. Age 22. Admitted to Garfield Memorial Hospital, March 17, 1905. Patient contracted gonorrhea fifteen days before admission to hospital. Ten days after the onset a left side epididymitis developed. Medical treatment and support were unsatisfactory, the pain demanding large doses of morphia that afforded slight relief. Examination revealed a very acute condition, with great swelling of epididymis and cord, the organ measuring twelve inches in circumference. The scrotal skin was inflamed and edematous. Operation March 19. Temperature 101° to 103°. Leucocyte count 18,600. The tunica vaginalis contained over an ounce of bloody fluid and particles of lymph. The serous membrane appeared identical with that of gonorrheal joints. Minute hemorrhages were noted over the epididymis especially. On puncture of the greatly enlarged epididymis tarry-looking blood and fluid escaped, but no pus. Cultures and cover slips were negative for gonococci. Twenty-four hours after the operation the temperature was normal, not again rising above 99.2°, the leucocyte count 12,000, and twenty-four hours later 9,000. Relief from pain was complete and permanent, no anodyne whatever being used. Forty-eight hours after the operation the drain was removed, followd by a little bloody discharge. Fairly firm palpation of the once-exquisitely tender organ elicited no pain. On the sixth day the patient was up and about, free of pain, the testicle being but slightly larger than its fellow. He was discharged on the tenth day, the wound being healed and testicle practically normal in size. Three months later, in the secretion obtained by careful massage of the left seminal vesicle and the left side of the prostate only, spermatozoa were demonstrated. Only the most careful examination would show which had been the diseased testicle.

Case II.—W. M. Age 28. Admitted to Garfield Hospital June 29, 1905, with a temperature of 103.4° and a leucocyte count of 14,600. He had had chronic gonorrhea for six months, and five days before admission an epididymitis began. Before entering the hospital his physician was giving him one half a grain of morphine hypodermically every three or four hours. Excessive tenderness and excruciating pain rendered examination out of the question. The organ was swollen to a circumference of ten inches. Operation on day of admission. Examination under ether revealed no areas of softening in the epididymis; the skin was red and showed marked inflammatory edema. The tunica vaginalis contained two and a half ounces of bloody fluid mixed with lymph. Practically the same picture was seen here as in Case I., except that there was much more lymph deposited over the epididymis and a more generally inflamed condition of the whole tunica vaginalis. The testicle appeared normal, and puncture of the tunica albuginea showed a normal condition. About forty punctures were made in the greatly inflamed epididymis; in the region of the globus minor a few drops of pus, containing gonococci, escaped. The skin and subcutaneous tissue were then dissected from the posterior aspect of the epididymis, and punctures made in this region evacuated a small amount of serum, blood, and pus. The small pus cavities were irrigated with bichloride, followed by salt solution, the rest of the operation being as heretofore described. In forty-eight hours the temperature was normal and the leucocyte count 11,000. The relief from pain was absolute and permanent. From now on the patient's recovery was uneventful, greater time being required for disappearance of the infiltration. He was up and around in ten days. I have been unable to examine this patient recently, but in a letter he states that there is no atrophy of the testicle and an almost complete absence of a former infiltrated epididymis.

Case III.—J. P. Age 36. Admitted to hospital October 10, 1905. He had suffered with epididymitis for the previous two weeks, and medical treatment had afforded very little relief. Since the onset of the trouble he has complained of sweats, chilly sensations, and continued pain in the testicle and back. Examination reveals a very tender and greatly thickened epididymis; the skin is rather tense, but not reddened or edematous. Operation October 14, 1905. Temperature 100° to 101°. The tunica vaginalis contained one and a half ounces of blood-tinged fluid, in which gonococci were demonstrated, but blood and agar cultures were negative. No pus was obtained from the epididymis on puncture. The relief from pain was instantaneous and complete, and in forty-eight hours the temperature reached normal. He was up and around on the fifth

day. On the eighth day, the wound being healed, he was discharged.

Case IV.—J. R. Age 21. Admitted January 16, 1906. Four weeks previous he contracted gonorrhea and seven days ago there developed an epididymitis. Medical treatment offered but little relief. On examination the testicle was very painful, the lightest palpation causing great agony. The affected organ was not much enlarged, its circumference being nine inches; the skin was not inflamed, but was slightly edematous. The epididymis and cord were enlarged and markedly infiltrated. On incision the skin was seen to be infiltrated, and on opening the tunica vaginalis a dram and a half of clear, straw-colored fluid escaped. That part of the tunica vaginalis covering the epididymis was covered with much lymph, and its parietal and visceral layers here were glued together; after these were separated there were seen to be present punctate hemorrhages and very marked general inflammation of the membrane covering the epididymis. Cultures taken on hydrocele agar and cover slips were negative. The epididymis was punctured over the globus major and its body, the result being an exudation of blood and serum, but no pus; but on puncture of the globus minor pus was found. A probe was inserted, and three or four drops of pus were massaged out, then the cavity was syringed out and the wound closed as previously described. Cultures from the pus were sterile, and no organisms could be found on cover slips. The wound was dressed on the second day, there being a slight ooze on removing the drain. Patient experienced no pain after the operation, and convalescence was uneventful. He was walking around, free of pain, on the sixth day. This case interested me as showing no redness of skin, even when pus was present.

Case V.—W. B. Age 22. Admited to the hospital December 15, 1905. He contracted gonorrhea November 30. A right-sided epididymitis developed in one week, from which he suffered excruciatingly, and on admission his expression was that of one enduring agony. Operation December 16. Temperature 100°. The tunica vaginalis contained one ounce of bloody-colored fluid. The epididymis was greatly congested and swollen; this was punctured about twenty times. Pus containing gonococci was obtained from the globus minor. A membrane of lymph was stripped off from the tunica vaginalis; this had all of the characteristics of a diphtheritic membrane, which upon removal left a granular bleeding surface. He had complete relief from pain after recovering from the anesthetic. Temperature was normal in thirty-six hours. On December 22 he had no pain; the induration of the cord and epididymis was much less. On December 26, when he left the hospital, the induration had disappeared and there was no pain on palpation.

Case VI.—J. T. Age 26. This case closely resembled the fourth case, except that no pus or organisms were found either in the epididymis or tunica vaginalis, but the relief was as marked and uneventful. Since the presentation of this paper three other cases have been operated upon, the results being uniformly good as regards relief of pain, lessening of infiltration, and rapid recovery.

THE EFFECTS OF ABSINTHE.

By EMMA E. WALKER, M.D.,
NEW YORK.

France as a nation has become so roused to the danger of alcohol and the essences, especially absinthe, which are in such common use in that country, that on December 29, 1900, the French government requested the Academy of Medicine to determine the comparative toxicity of the various alcoholic beverages in use with a view to proscribing the ones most dangerous to health. After an investigation it was suggested by one of the committee that absinthe alone be put into the forbidden list.

In France absinthe is known as the "scourge," the "plague," "the enemy," and "the queen of poisons." Absinthe is a liquor of an emerald green color, consisting of from 47 to 80 per cent. of alcohol, highly flavored with the aromatics, wormwood, anise, fennel, coriander, calamus aromaticus, hyssop, and marjoram. The special variety of this drink depends upon the proportions and kinds of these flavors composing it. Its quality will also depend upon the quality of its constituents. Since any unpleasant taste may be easily concealed by the strong aromatic used, the alcohol employed in this liquor is frequently very impure.

Absinthe heads the list of toxic essences. The ordinary absinthe contains a far larger percentage of alcohol than does whiskey. Consequently its toxic effects are far greater than are those of whiskey, for to the increased amount of alcohol there is added the deadly wormwood.

In France, according to the law of March 26, 1872, it was declared that the commerce and sale of the essence of absinthe ought to be carried on by the pharmacists according to the law on the sale of poisons.

Absinthe, *Artemisia absinthium*, is the common wormwood, the bitterness of which has passed into a proverb. Absinthe is quoted to contain only one-third of 1 per cent. of the oil of wormwood, to which are due the characteristic effects of the beverage. The bitter principle of absinthium, *absinthin*, is a narcotic poison. The coloring matters used in absinthe are often very deleterious; in fact not infrequently copper salts have been used in order to produce the green color.

Absinthe is chiefly used in France, and especially in Paris. It was introduced there after the Algerian war of 1844-7 by the soldiers, who, on their campaign, had been advised to mix absinthe with their wine as a febrifuge. The use of absinthe rapidly increased in France with such disastrous results that it has been described by French physicians as constituting a graver danger to the public than alcohol itself.

The habit of absinthe drinking is a most insidious one, and when it is once indulged it seems almost impossible to break. Thirst is more exacting than hunger. It is often a purely imaginary sensation. "Arrived at a morbid degree, the passion for drink is not only a vice which blights equally the reason, morality and justice, but is a veritable mental malady" (Paul Jolly). "The poisonous and inebriating effects produced in those who drink the liqueur of absinthe or cream of absinthe is undoubtedly due more to the wormwood than to the alcohol" (Trousseau and Pideaux).

The effects of the internal use of absinthe naturally fall into two groups, due respectively to the chief ingredients of the liquor—alcohol, and the essential oil of wormwood, which has a special affinity for the brain and nervous system in general. These

groups may be subdivided according to their physiological, pathological, and mental effects.

The effects of alcoholic beverages in general are too well known to be dwelt upon in much detail. Atwater, one of the American Committee of Fifty who have recently investigated the drink problem, declares that alcohol, when taken habitually in excess, is ruinous to both health and character. In large enough quantities it is a poison. According to Abel, alcohol does not produce "any persistent increase of muscular power, but only enables a brief spurt to be made, which is soon followed by a depression of energy to below the normal." This writer also says that the "moderate" quantity of alcohol is "represented by one, or at most two, glasses of wine (10 per cent. alcohol) or one pint of beer, or their equivalents in terms of alcohol, in the twenty-four hours." Lauder Brunton states that two fluid ounces — rather less than the ordinary sherry glassful—is the extreme limit in twenty-four hours. No authority questions the fact that an excess of alcohol impairs certain cerebral functions—attention, memory, self-control—as well as causing insanity in many cases. But what constitutes excess will depend to a certain extent upon the individual, the occupation, and other conditions.

Physiological and pathological changes are caused by the use of both alcohol and absinthe and are the keynote to the mental and physical effects of these two drugs.

One of the first effects of alcohol is dilatation of the blood-vessels and a quickening of the circulation. After the spurt of the stimulation, due to the acceleration of circulation, comes the stage of diminution of mental power. The superficial blood-vessels become dilated after a moderate amount of alcohol, which might account for the effect on the sexual organism sometimes noted.

Alcohol in small quantities causes an increase in the secretions and an increase in peristaltic movement. Large quantities diminish the secretion of gastric juice and cause active congestion of the mucous membrane of the stomach and a great increase of mucus. After the absorption of alcohol there is less tissue change, hence the tendency to the accumulation of fat.

The Pathological Effects.—By repeated indulgence in alcohol the blood vessels which supply the nerve centers with blood become altered, and the nerve centers themselves also are changed. The nerve cells and fibers to which the activity of the nerve centers is due are supported and bound together by connective tissue. In chronic alcoholism this tissue is much increased. The result is pressure on the nerve cells and fibers, which causes them to waste away.

The Mental Effects.—The effect of the narcotic action is to decrease the close relationship that exists between the individual and his environment and the delicacy of his power of adjustment to external circumstances. The ordinary self-restraint which he has previously shown, together with the consideration of his surroundings, disappears by degrees. The alcoholic becomes more egoistic and selfish, and his surroundings seem less important to him. His mental faculties are unrestrained, and they may be compared to a fly wheel without a brake. He becomes vacillating, and his moral sense is diminished. The poison has destroyed his will. Alcoholic liquors pervert the most important and noble faculties of the man who abuses them and make him old before his time. His brain suffers. His speech becomes more free. He loses his discretion. He repeats his own, as well as others' secrets. His imagination becomes more lively. His emotions are more easily excited—his affection, his hate, or his pugnacity. The memory is impaired. "Mental concentration and power are lessened and the subject becomes 'willless (abulic).'" The gradual disappearance of his faculties proceeds in an inverse order to that of their development. "Alcohol makes man first a child, then a beast."

The chief action of alcohol, according to certain recent investigators, is that of a paralyzant. The nervous centers are affected in the following order: First, the judgment and self-restraint, then the power of perceiving the relations of external circumstances to the individual. He becomes ridiculous, foolhardy, stupid, maudlin, or quarrelsome. After the cerebrum is affected the cerebellum follows, and consequently the power of coordination is lost, and the man staggers. The spinal cord and the medulla are next disturbed.

When the circulation is stimulated a pleasurable sensation of well-being is produced and a childish joyousness. When the pleasure is greatest there is greatest danger of the victim being led into excess.

From the habitual use of alcohol a chronic poisoning develops, even when the beverage has not produced drunkenness. The artificial excitement, due to alcohol, soon gives way to nervous depression and feebleness. The continued use of alcohol leads to chronic disease of the different organs.

Absinthe acts, as would be expected from its composition, like an alcoholic liquor, except that certain features are exaggerated and some new features are added, for it has a marked physical action of its own. The effects of absinthe develop far more rapidly than those of alcohol. What has been said of alcoholism can also be said of absinthism: "Alcoholism is primarily a physiological disease comprising: 1. Paralysis of the inhibitory power of the will; 2. A temporary amnesia; 3. A temporary affective and intellective modification of the personality."

The effects of absinthe in a small dose are giddiness, vertigo, muscular disorders, and convulsive movements like those produced by successive electric shocks. In a stronger dose it causes attacks of epilepsy, more or less violent, which are not produced by alcohol. Brunton declares that these convulsions are due to the action of absinthe upon the medulla—not upon the cerebrum. The end is favorable, as a rule, but may be fatal. Corning has investigated the chronic influence of this drug upon the brain, especially its higher centers, and emphasizes this effect. Brunton says that absinthe is a spinal stimulant.

The Physiological Effects.—In small quantities the oil of wormwood quickens the heart's action, and in larger ones it is a narcotic. It slightly increases the secretions. Amory, in his experiments with absinthe, found that after its administration the nervous centers, especially the cord, were congested. Magnan found the cerebrum and spinal cord congested.

The Pathological Effects.—Amory found an infiltration of blood in some places in the nervous centers. The heart was soft and flaccid. Phillips states that the membranes of the brain and cord are always injured. The lungs are congested, and extravasations of blood are found in the membranes of the heart. Absinthe drinking is followed by a softening of the brain and general paralysis, more often than is the drinking of alcohol.

The Mental Effects.—Lanceraux says that the danger incident to the use of the drug is on account of: 1. Its action on the nervous system; 2. The

state of denutrition resulting from its continuous use. Cushny states that the oil of absinthe causes marked excitement and convulsions. In cases of poisoning the symptoms related to the disturbance of the nervous system predominate. The brain stimulation causes different kinds of convulsions. The epileptiform fits observed after its ingestion are due mainly to the action of this drug on the cerebrum, although other parts of the central nervous system are involved. Cadeac and Meunier sum up the mental effects of this drug as follows: Somnolence, torpor, loss of memory, intellectual paralysis, dullness, complete loss of will, and brutishness. These effects are, as a rule, observed in the absinthe drinker.

Absinthe Epilepsy.—Abel says that absinthe gives rise to hallucinations from the very first. States of delirium are often observed between the epileptic attacks, and there may be delirium without epileptic seizures. For some time it has been noticed that results other than those due to alcoholism take place in absintheurs. Marcé and Magnan did some experimental work with animals in 1864. In one case Magnan gave five grams of the oil of wormwood by mouth to a dog. The animal had an "attaque d'epilepsie" in half an hour. A second atack developed ten minutes later, after which hallucinations occurred. The dog savagely attacked the bare, white wall, undoubtedly thinking that it was an enemy. Binz remarks that it is plain to see that a drug which so markedly stimulates the brain, will, by continual use, gradually bring about such changes in the cells, the vessels, and the membranes of the brain, as finally to develop that type of delirium tremens which is complicated by characteristic epileptic seizures.

Danillo relates the following incident: A medical attendant observed a man who had swallowed about four teaspoonfuls of the oil of wormwood. Convulsions of the face and limbs, loss of consciousness, and violent constriction of the throat, took place within a few minutes after the oil had been taken. Recovery was complete, but, as in the case of most epileptic attacks, the man had no recollection of the beginning of the fit. The victim of epileptic mania does deeds of violence with no consciousness of the same; nor has he any memory of them after they are done. This type is often developed by habitual indulgence in absinthe. Victor Horsley and Magnan, in their studies of epilepsy, induced the convulsion by injecting absinthe. Horsley concludes that the principal seat of the disturbance must be the cerebral hemispheres, and especially their cortical mantle.

Epileptic Insanity.—"The sudden and local discharge from the cells of the cerebral cortex may cause mental as well as motor disturbances." The mental disturbances may occur without the motor disturbances. Epileptics are usually gloomy, irritable, and irrascible, and "pass rapidly from anger to suavity." Epilepsy may develop into acute epileptic insanity; it sometimes occurs without any convulsive attacks. The mania may begin suddenly. The return to sanity is usually sudden, and is accompanied by forgetfulness of the acts performed.

Equivalents of the Epileptic Attack. — Instead of ordinary convulsive attacks of epilepsy, a person may have a variety of acute mental disturbances. "Epileptics may unconsciously, automatically, and with apparent purpose, perform a number of coordinate acts. Homicidal, obscene, or pyromaniac acts may thus be done by epileptics, or intricate maneuvers, such as require the use of tools may be accomplished. Subsequently, as a rule, they have no knowledge of such acts. The procursive fit may, in a sort of status, be prolonged, so that the patient may make journeys of several hours' or several days' duration, during which the conduct is so natural as to attract no notice. Self-consciousness usually is rather abruptly restored, and they are astonished to find themselves at a distance from home, with an intervening blank period of time" (Church and Peterson).

It is said that psychic degeneration is manifested in 60 to 80 per cent. of all epileptics. Probably not more than 10 to 15 per cent. of epileptics develop insanity; however, the proportion is so large as to show a close relation between this functional cortical malady and mental disorders. "When progressive epileptic degeneration occurs, it manifests itself by the following symptoms: Slowness of ideation and articulation; abnormal irritability of temper; hypochondriacal depression; paranoid outbreaks of various kinds, and dementia."

The various effects of this deadly drug on the whole man are so closely interwoven, the one with the other, that it would appear impossible to draw a sharp line of demarcation between any two. Again, in considering the effects of the beverage, absinthe, the effects of alcohol must also be considered.

The chronic mental disorders of the chronic alcoholic result in an insane jealousy, which is due to the deteriorating influence of alcohol on the generative organs. It has been noticed that some men, as they grow older, indulge in sexual excess as well as in alcoholic excess. When the tone of the generative organs is lowered, stimulants do not improve their condition, but rather weaken than strengthen them.

There is on record the history of one family, in which the progenitors indulged in alcoholic beverages, and among their thirty-three descendants there were four prostitutes. Crothers states that moral insanity follows all use of alcohol. The sexual conduct of those morally insane from the use of alcoholic stimulants is without restraint. Many who exhibit the symptoms of moral insanity appear little, if any, changed in other respects.

From the point of view of absinthe epilepsy, it is known that in many epileptics the sexual instinct is most intense. It may be that the cerebral changes incident to the epileptic outbreak cause an abnormal stimulation of the sexual instinct. In many cases this excitement is not active during intervals, but is shown only in connection with the epileptic attack or in the post-epileptic period. "Nobody questions the harm wrought by wormwood in its rôle of servant to human debauchery." Through the entire career of chronic alcoholism "runs the thread of mental degradation involving moral obliquity." The poison produces a physical degradation, which is followed by mental and moral palsy. Lying becomes second nature; conscience is deadened. Kerr says that "the sexual function is responsible for much periodical excitation of inebriety."

The temporary effects of absinthe will, of course, depend upon various factors, most important of which are the quantity of the beverage taken, and the condition of the consumer at the time of indulgence. Kurz and Kraepelin show by experiments that the influence of one dose of alcohol of two and four-fifths ounces does not pass away at once. Its after-effects last longer than twenty-four hours. If this dose is repeated the effect is gradually increased. After twelve days' action the effect is very apparent in "a depreciation of faculty to the extent of twenty-five to forty per cent." The effects of larger doses of alcohol, especially when repeated, will not dis-

appear after a night's sleep. It is possible that there may be a dose, the effects of which may not be noticed. This would be a difficult question to decide. This amount would vary. It would be on the average less than seven and a half grams, or less than the alcohol contained in a half glass of port.

The effects of a moderate quantity of alcohol have already been referred to. A feeling of well-being and gayety, and a condition of irresponsibility are most apt to develop at first. Even in small quantities alcohol does cause serious structural changes in various parts of the body. In a short time only, important organic changes are produced in the nerve cells of the brain and in the central nervous system.

It is well known that alcohol affects different individuals in different ways. Biggs refers to a case showing the difference in the temporary toxic effects of excessive indulgence in alcohol on two college chums. In one case it produced great disturbance in the power of locomotion, but the mind remained clear, while in the other case the mental power was much disturbed, but the locomotor apparatus was unaffected. They became companions at such times, and so helped each other out.

The one who indulges in alcoholic beverages or absinthe loses temporarily the power of good judgment and the power of resistance to any influence or persuasion that is brought to bear upon him. Phillips says that large doses of absinthe act first as an excitant, and produce a pleasant warmth which permeates the whole body. The temporary effects of absinthe itself are well shown in a case reported by Dr. Robinovitch. The drinker within the course of a few days and nights of heavy indulgence in absinthe suffered from an active and very painful delirium. The action of absinthe causes almost immediate convulsive manifestations. Magnan states that the essence of absinthe causes delirium in the dog. In one of his experiments, twelve minutes after an epileptic attack, the dog all of a sudden, without any provocation, "straightens itself upon its feet, the hair disheveled, its looks angry, the eyes injected and brilliant; it directs its looks toward any point, although there is nothing to attract its attention; it stiffens, and with neck stretched, the animal is ready to jump; it advances and retreats successively; it barks with rage and struggles furiously, grinding its teeth, jumping abruptly to catch its imaginary enemy; it then shakes its head from side to side, the teeth close together, as if ready to tear its prey. Little by little it becomes calmer, again gazes, growling, in the same direction, then is reassured entirely."

Magnan declares that "this delirious attack, so suddenly developed, explains the precocious delirium of absinthe drunkards. . . . Under the influence of small doses of the essence of absinthe, the dog stops suddenly, stupefied, the head lowered, the tail hanging down, the appearance dejected, a stranger to all that is going on. It is in a condition of *petit mal*."

In the acute form of absinthism, vertigo and nausea are prominent symptoms, besides the effects of the alcohol. According to Amory, the immediate effects of absinthe are epileptic convulsions and nervous debility. One overdose of absinthe will produce epileptic convulsions. When absinthe is given to animals in small doses, it causes giddiness and muscular jerking. In large doses it produces epileptic convulsions, and also delirium and hallucinations. This delirium develops very suddenly, and the hallucinations cause appearances of fright and agitation. In man the giddiness and muscular jerking are not so marked as in animals. They might be even unnoticed if one were not on the lookout for them. The trembling and giddiness which appear might be thought to be due to alcohol alone. But where there is complete intoxication there are epileptic seizures which are not caused by alcohol.

Marcé, Trousseau, Pidoux, and Motet have determined that a small dose of absinthe will cause vertigo, muscular disorders, and convulsive movements. In a stronger dose it causes attacks of epilepsy more or less violent.

The attack of insanity of the absinthe drinker is very similar to that produced by alcohol, but, in addition, according to Magnan, there are often epileptic seizures, and the hallucinations are very sudden in the onset and quickly reach their acme.

In certain experiments, the administration of this drug was followed by diminished reflexes and a condition of depression. In acute, as well as chronic intoxication, after the stage of depression and diminished reflexes, violent epileptiform convulsions occurred, and a distinct increase of reflex irritability.

Amory gives a comparative table of the temporary and permanent effects of absinthe with those of alcoholic beverages generally, founded on the experiments conducted by Magnan and himself:

Absinthe.	Alcohol.
Animal perfectly well for fifteen minutes, at the least, after the ingestion, with the exception of a few muscular twitchings and a slight uneasiness.	In a very few minutes symptoms of inebriation, resulting in torpor.
Muscular agitation, commencing in the *anterior* portion of the body.	Paralysis, commencing in *posterior* extremities, and then extending to the anterior.
No paralysis.	Paralysis of both posterior and anterior extremities in succession.
Epileptiform convulsions and rigidity, resulting in a speedy death.	No convulsions. Stupor, coma, resolution, and a gradual death.
No apparent lesion, except perhaps a slight cerebral congestion, showing the cause of death to be intoxication by the poison.	Lesions of the brain and of the alimentary canal; gastritis and enteritis might have supervened, had the animals lived long enough for their development.

Differential and characteristic signs which govern the positive diagnosis between the effects of alcohol and absinthe are epileptic attacks, vertigo, early hallucinations, delirium, and inconscient delirium which sometimes follow the attack.

Simple alcoholic delirium is far slower of development. The use of absinthe produces convulsive manifestations almost immediately. The epileptiform attacks in most cases of simple alcoholism require a certain time—some years—for preparation of the brain before they manifest themselves. Absinthe "convulsions are an exact reproduction of the epileptic cycle: tonic convulsions, followed by clonic ones, rapid and short at first, then more and more slow and distant, ending in rest."

The delirious attacks of absinthe develop suddenly, just as "after the administration of certain poisons, of hyoscyamus, belladonna, or stramonium, and this rapidity in the development of the intellectual disturbances is one of the distinctive characteristics distinguishing the action of absinthe and that of alcohol."

Robinovitch says that in the case of the absintheur "the whole clinical tableau of alcoholic poisoning seems to be condensed, so to speak, within the short-

est possible space of time. The excitation of the senses, the delirium, the muscular cramps, the dizziness, vertigo, and finally the *true epileptic* convulsions set in, and follow one another in rapid succession. Where years are necessary for alcoholic morbid changes to be expressed clinically by epileptiform attacks, one year or even less, suffices to bring about *true epileptic* attacks by the abuse of absinthe."

Absinthism differs in various ways from alcoholism. In the former are manifested hallucinations and terrible dreams, enfeeblement of the intellect, and stupor, all of which may develop rapidly without any muscular tremor. If this tremor does exist, it is usually confined to the upper extremities. Absintheurs are restless at night. They suffer from nightmare, nausea, lack of appetite, vomiting, mental dullness, and sometimes delirium or mania. Mental deterioration progresses. The power of concentration of memory is impaired, and the patient loses his will power. He becomes indifferent to the welfare of both himself and his family and friends. Instead of the simple muscular tremor of delirium tremens, as is seen in the alcoholic, the epileptic fit is seen in the absinthe drinker. The fit recurs from time to time. If the habit is overcome during the early stages the fits cease. But if the indulgence is continued the intellect is permanently deranged and paralysis and death result. The morbid changes which develop vary according to the individual predisposition. Sometimes the fits are more like an attack of hysteria. Absintheurs have hallucinations of sight and hearing which do not represent a condition like delirium tremens. The victims of this habit become absolute physical and moral wrecks.

Lanceraux says that chronic absinthism has developed at the end of eight, ten, or twelve months in young women, or even girls from eighteen to twenty years of age.

Cirrhotic degeneration of the liver, kidneys, and heart is one of the effects of chronic alcoholism. Muscular tremor and incoordination are marked. The chronic form of alcoholism differs from that of absinthism, as has been said, mainly in respect to the epileptoid attacks and the early development of general paralysis; Gautier says also by the frequency of hyperesthesia in the iliac fossæ especially.

In general the effects of absinthe are like those of alcohol, but in the former they develop much earlier, and are of a severer nature. In absinthism there is also a more striking disturbance of the nervous system.

The writer takes this opportunity to acknowledge her great indebtedness to the many original investigators in the subject treated of in this paper. Their work has been freely consulted and quoted in this brief review.

29 East Twenty-Ninth Street.

Acute Yellow Atrophy of the Liver in Pregnancy.—G. Acconci states that acute yellow atrophy of the liver is rare in pregnancy, and is generally fatal both to mother and fetus. The etiology is obscure, but the author concludes, from the study of two cases observed by him, that there is no specific cause, but that any of the factors that produce it in the male may act in pregnancy as well. It may also be the result of an autointoxication of severe type due to the pregnant condition. It may come on as the aggravation of a slight icterus or may be a morbid entity. Pregnancy generally affects unfavorably any anatomical lesion of the liver. The same toxin that affects the mother may injure or destroy the fetus. The symptoms generally come on insidiously rather early in pregnancy and advance to a condition of stupor in which the fetus is delivered. The patient continues in a deep coma until death releases her.—*Annali di Ostetricia e Ginecologia*, March, 1906.

ROENTGENOGRAPHY OF THE STOMACH.

By Max Einhorn, M.D., and L. G. Cole, M.D.,

New York.

Rieder,[1] Holzknecht,[2] Williams,[3] and Hulst[4] have recently succeeded in taking good roentgenographs of the stomach. The method consists in giving the patient, when the stomach is entirely or partly

Fig. 1.—*X*-ray photograph of stomach (negative) of Dr B., taken in standing position. The greater curvature extends just to the navel

empty, a pint of milk into which one ounce of subnitrate of bismuth has been suspended by thorough mixing. The patient is then immediately skiagraphed in a standing or recumbent posture. By

Fig. 2.—Skiagraph (negative) of stomach of patient H. standing. The stomach is somewhat dilated and prolapsed, extending a hand's width below the navel.

holding a photographic plate directly over the abdomen the Roentgen picture can be obtained. The time of exposure is usually ten or fifteen seconds.

The writers have examined a considerable number

of patients with the *x*-rays and have convinced themselves that this method is an excellent one. It has the great advantage that no instruments whatever are introduced into the stomach, and that it permits

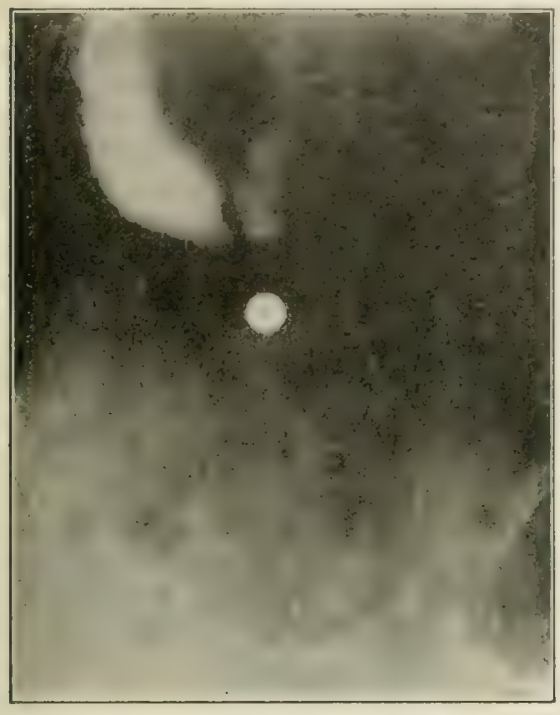

FIG. 3.—Skiagraph of same patient (H.) lying on his abdomen The greater curvature extends to about two fingers above the navel

also an investigation of the colon by exposing the patient to the rays a second time on the day following. The accompanying illustrations are reproduced from roentgenographs obtained by us.

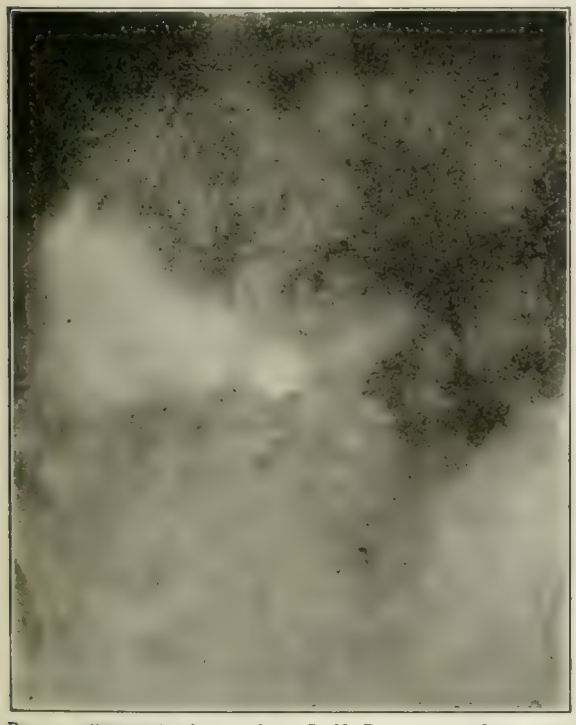

FIG. 4.—Skiagraph of a patient, O. N. P., 3 years after a gastroenterostomy (standing). The stomach extends to the navel, it shape is triangular.

The subnitrate of bismuth should be taken immediately before the skiagraph is made, as part of it passes into the duodenum very soon after it enters the stomach.

A coin is placed over the umbilicus and a wire may be placed around the body at the crest of the ilium and another at the lower edge of the ribs to serve as landmarks in making the skiagraphs.

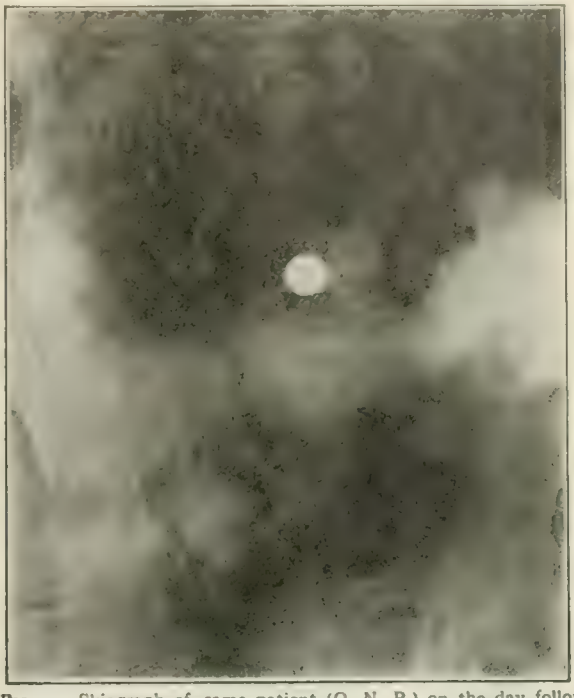

FIG. 5.—Skiagraph of same patient (O. N. P.) on the day following the ingestion of bismuth, stomach being empty. To the right and somewhat above the navel a Murphy button can be distinctly seen. It has remained in the stomach after a gastroenterostomy for the last 3 years.

The plate is placed against a wall and the patient stands with the abdomen pressed against it with sufficient force to hold it in position.

The anode is placed opposite the third lumbar

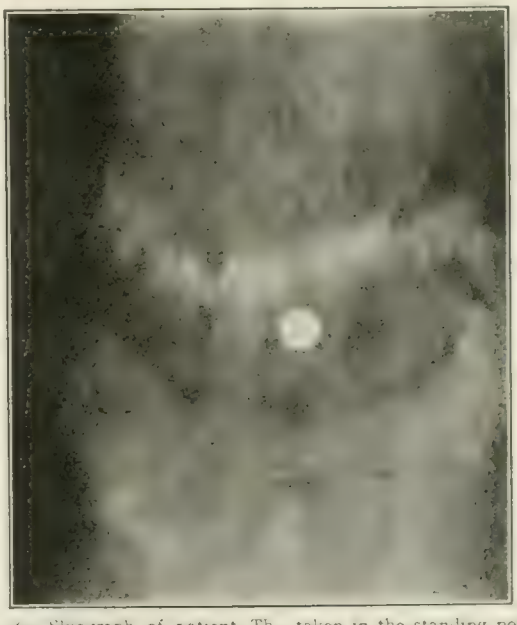

FIG. 6.—Skiagraph of patient Th., taken in the standing position the day following the ingestion of bismuth into the stomach. The outlines of the colon are shown to be normal.

vertebra and the patient is instructed to hold his breath while an exposure of from ten to thirty seconds is made. This shows the position and shape of the stomach in the standing position. Another skiagraph made in the prone position with the abdomen flat on the plate and the anode vertically over the third lumbar vertebra will show the position and shape of the stomach in the recumbent position. In

making the skiagraph care should be exercised not to interpret the shadow of a protruding abdomen as a distended stomach.

In the case of H. a great difference is seen in the position of the stomach according as the subject was

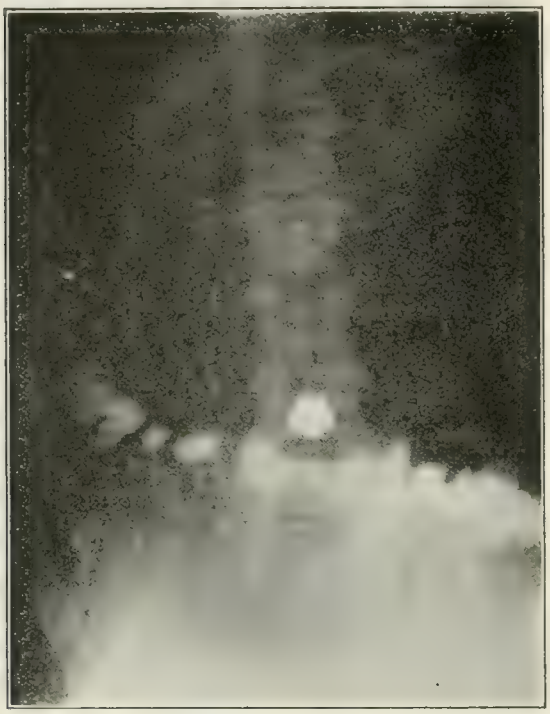

Fig. 7.—Skiagraph of patient H. on the day after ingestion of bismuth. The transverse colon is somewhat prolapsed.

standing and prone. The skiagraph (Fig. 3) showed that the stomach returned to its normal position when the patient lay on his abdomen.

REPORT OF THREE CASES OF POTT'S DISEASE AND ONE CASE OF COXALGIA OCCURRING IN ADULTS AND PRESENTING UNIQUE FEATURES.*

By J. TORRANCE RUGH, M.D.,

PHILADELPHIA.

ASSISTANT ORTHOPEDIC SURGEON TO THE JEFFERSON HOSPITAL; ORTHOPEDIC SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

The following cases illustrate the very frequent observation that tuberculosis knows no law beyond that common to all diseases. One case may present a typical set of symptoms which persist throughout a typical course, while another shows no regularity either in the onset of the symptoms, their sequence, or the course of the process, yet both will present the same pathological findings and are clinically the same disease.

Case I.—Miss M. W., aged 71 years. The family history was good, there being no tuberculosis or other transmissible disease or condition on either side of the family. She was descended from a sturdy and long-lived race. Her personal history was good, her only complaint being a uterine prolapse of many years' duration which necessitated the constant wearing of a stem pessary. In May, 1903, she began to suffer with pains in the stomach. She had marked indigestion and was treated for the condition in an institution. Improvement followed, and she became able to take much more nourishment with greater comfort to herself, and gained strength, though still remaining quite debilitated. In June, 1903, she began to have weakness in both legs and difficulty in walking and entered a hospital in a Western city for treatment. Here she remained for three months and then became able to walk around. In October she returned to her home in Pennsylvania, but in November was forced to go to bed. Nothing specifically was done for her during this time beyond the attention given to her general health, the condition which was evidently developing in her spine being disregarded. This condition as first noticed by her people about this time was a small knuckle in the dorsal region, involving the eighth and ninth vertebræ. This was considered of no moment, and she remained bedfast. In April, 1904, spastic contractions of the feet and legs began, and, though they were not very severe, they were quite annoying. They increased in severity, and in a month or so it became necessary to attach weights to the feet to prevent the legs from remaining completely flexed upon the abdomen. Shortly after this the bowels and bladder became affected and incontinence in both developed. She continued in this state until the fall, when slight improvement took place. Spasm of the legs became less pronounced; partial control of the bowels and bladder was regained; her appetite improved, and she appeared brighter.

I saw her with her physician in December, 1904, and found her nearly helpless in bed and with a well-pronounced kyphos involving the seventh, eighth, and ninth dorsal vertebræ, and, in view of the improvement which had occurred, advised plaster-of-Paris to be applied in the position of extension. Her knee-jerks were exaggerated and there was still some spasticity of the lower extremities. She also had girdle pains just over the stomach. A jacket was applied by the physician, but had to be removed after a few days on account of the discomfort and irritation. In February, 1905, she began to fail, and in a month or so died. No abscesses had formed, but the paralysis had become complete and the resulting exhaustion in one of her age proved too much for her.

The interesting features of the case are the development of a primary tuberculosis of the spine in a woman seventy years of age, with no apparent causative history and the early and rapid onset of paralytic symptoms even before the appearance of the knuckle in the spine.

Case II.—J. M., aged 50 years. He was born in Ireland and followed the sea as a cook until stricken with disease. His father died at the age of 30 from rheumatism (?). His mother died at the age of 40 from heart disease. One brother and one sister are living and well. No family history of tuberculosis, syphilis, malignant, or other disease. His personal history reveals nothing of the diseases of childhood, but states that he was normally healthy. As a young man, he says, he had inflammatory rheumatism, but also admits having had several attacks of gonorrhea

*Read by title at the nineteenth annual meeting of the American Orthopedic Association, held at Boston, June 6, 7, and 8, 1905.

about the same time. These attacks were followed by a urethral stricture, but it was thoroughly dilated and he has had no trouble from that source. He had pneumonia and pleurisy at 23 years of age, chills and fever at 33 years, and enteric fever at 37 years, but from all these he made a good recovery.

In July, 1903, when he was 47 years of age, both testicles were removed on account of tuberculous degeneration, and a sinus persisted from one of the wounds for over a year. In March, 1904, he entered a hospital for treatment for indigestion and "stomach trouble," but was later discharged for insubordination and refusal to take his medicine. (Note the similarity in the onset of the symptoms in this case and the one just chronicled.) At this time a very small knuckle had formed in the lower dorsal region of the spine, and plaster-of-Paris was applied for a few months and then a brace was made for him. Both of these afforded him much relief, and he disappeared from observation until May, 1905. At this date he came under treatment at the Orthopedic Dispensary of the Jefferson Hospital for pain running down the legs and in the lower part of the abdomen. The brace proved inefficient and he would not go to bed, though there were symptoms of beginning pressure upon the cord. He grew worse, and soon walking became impaired. He complained of cystitis, and a careful examination in the Genitourinary Department of the same hospital developed the fact that he had a tubercular kidney. He was treated for this condition, and, improving somewhat, again disappeared. He went to several different hospitals for treatment and was finally admitted to one where, after observation, laminectomy was advised to relieve the spinal pressure. He was satisfied to have the operation done, but was not favorable to the operator. He then consulted Prof. W. Joseph Hearn, who in turn asked me to see him, inasmuch as I had had previous knowledge of him.

Examination showed marked prominence of the seventh, eighth, and ninth dorsal vertebræ, with paralysis of the lower extremities, though sensation was much less interfered with than motion. The knee-jerks were exaggerated, Babinski's reflex was pronounced, there was loss of control of the bowels and partly so of the bladder, and a marked feeling of constriction at the level of the umbilicus. His general condition was good and he had taken on much weight during the past year. Examination of the urine showed a normal condition in spite of the findings of a year previous.

On May 13, 1906, through the courtesy and with the assistance of Professor Hearn, I operated upon him, removing a portion of the laminæ of the seventh dorsal vertebra and all of that part from the eighth and ninth. The cord bulged out quite markedly after the removal of the bones and was found free from pressure at both the upper and the lower ends of the wound. The membranes were not opened, as it was not thought anything would be gained thereby. The wound was sutured with silkworm gut and a few strands of the same material were used to secure drainage.

On May 21, the stitches were removed. The wound healed by first intention. A plaster-of-Paris splint was applied as a trough to the back and the body firmly bound to it. Cramping of the legs is only intermittent now.

May 25.—Can now void urine voluntarily. There is also considerable return of power to the feet and legs. Condition excellent and at no time has the temperature been above 99.4°.

After this he gradually improved in strength until on June 20 he was able to sit up in bed with his brace on. He left the hospital on 6/30 and gives every indication of regaining his normal strength as he has his weight.

Especially interesting in this case is the primary focus of disease in the testicles with secondary infection of the spine and kidney and the subsidence of the activity of the disease in each focus for the present at least. As he is a rugged looking man, there would seem no reason to anticipate aught but recovery in his case. (As first reported, this record was not nearly so complete, but the delay in publishing this paper has enabled the author to give a much more interesting and satisfactory history of this unusual case.)

Case III.—M. T., born August 31, 1869. Family history is very good, there being no tuberculosis, cancer, or other disease present. Personal history is good. Had mumps, measles, and whooping-cough during childhood. At fourteen years of age he developed malaria, but was cured in a short while. In 1887 (eighteen years of age) he first experienced difficulty in straightening himself after being bent forward. He had no injury and was working on his father's farm at the time of the onset of the trouble. This symptom persisted for two years and grew gradually worse. In 1889 (twenty years of age) sharp pains developed in the lower abdomen and extended down the legs. At this time he was unable to bend in any direction, but he continued his work as a farmer as best he could. There was no trouble with the bladder or bowels. Two years later (1891) he first noticed a very small lump in the middle of the lumbar region. It grew gradually larger, but no treatment was used for the back. In 1894, he was compelled to go to bed for seven months, beginning in September, and could do no work of any character. No mechanical treatment was employed at any time, but the supine position in bed allowed the process to subside somewhat, and he recovered sufficiently to get about. He suffered for the next ten years with girdle pains and sharp pains in the pelvis and legs and was not able to work as he had done before. He was treated in the spring of 1904 for myelitis and was much benefited, but in September, 1904, he noticed a small lump in the right thigh, just below Poupart's ligament. It grew gradually larger, but caused him no pain. When he first came to the Jefferson Hospital for relief from this tumor (in April, 1905) it was about the size of a child's head. There was also a large tumor to be felt in the right iliac fossa and fluctuation between these two was easily demonstrated. The tumor on the thigh had been variously diagnosed, but on April 24, 1905, it was incised at the lower angle (about eight inches above the knee-joint), and again close to the anterior superior iliac spine and just above Poupart's ligament. About two quarts of tubercular pus were removed, and after thoroughly cleansing the cavity and washing out first with peroxide of hydrogen and then with 1-4000 solution of bichloride, the upper incision was closed while slight drainage was maintained through the lower wound. Both wounds healed and a steel brace was applied in August, 1905, and is still being worn. The present condition indicates that the disease is being eradicated and will ultimately be cured, as he has been working ever since the brace was applied, and he feels fairly comfortable. As his work is that of a driver

of a milk wagon on a route in a small city, his condition is certainly a hopeful one.

The interesting features of this case are the extremely slow onset of the disease, in spite of the heavy work constantly performed and in the absence of all mechanical treatment, seven years having elapsed before he was forced to give up the first time, the slight degree of deformity which is now present (1906), and the very favorable outlook for the case since the beginning of proper treatment.

The following case of coxalgia is of unusual interest as illustrating the impossibility of pronouncing a case of tuberculosis cured. Almost everyone has seen cases in which the diseased process has remained latent for ten or even twenty years, but seldom does one see a case that has broken out after a quiescent period of sixty years.

Case IV.—J. J. M., aged seventy-two years; a saddler by trade. His appearance was that of a small, spare man, who, though looking as old as he confessed, was yet very well preserved. He applied for treatment at the Orthopedic Dispensary of the Jefferson Hospital in the summer of 1901 and gave the following history: When eight years of age (in 1837) he contracted hip-joint disease and was brought by his parents for treatment at the small hospital attached to the Jefferson College. He was seen by Dr. George McClellan, one of the founders of the college, and at that time the Professor of Surgery, who advised the application of a box frame to the leg to act as a splint and to "draw the leg down." Abscesses developed later and were opened by Dr. McClellan and drained. When he was twelve years of age (1841) the abscesses had healed and the hip was ankylosed. He grew to manhood, followed his trade, married, and reared a family of four or five children. He had always enjoyed good health and led a peaceful and useful life. In 1901, when he was seventy-two years of age, without any known injury or cause, pain began in the hip and thigh, and a few days before coming to the Jefferson Hospital three of the old sinuses reopened and were, when I saw him, discharging purulent matter in every way similar to tuberculous pus. The character of the sinuses and pus and the manner of onset left no doubt but that it was a relighting of the old process from which he had apparently recovered sixty years previously. He attended the dispensary for a month or six weeks, but, experiencing no improvement from the treatment, ceased his visits, and I have not been able to locate him to ascertain the outcome of the disease.

A Contribution to the Etiology of Lateral Curvature of the Spine.—M. Böhm gives *x*-ray pictures of three cases which present certain peculiarities in the lowest lumbar vertebra. The general conditions may be stated by saying that they consist of an anatomical and apparently congenital malformation in the sense of an incomplete development of a sixth lumbar vertebra, with more or less fusion to the fifth lumbar vertebra and to the sacrum. The question arises; Do these peculiarities represent the cause of the curvatures in the cases reported, or are they only incidental thereto? The author replies to this query as follows: The top of the sacrum and the fifth lumbar vertebra are the foundation of the human spine, and only as long as this base is normal, that is, symmetrical, the symmetrical development of our spine is possible. Consequently, if, for instance, a supernumerary lumbar vertebra between the fifth and the sacrum should occur, the symmetrical development of the spine would not be disturbed, as long as this intercalated vertebra is in itself symmetrical. On the other hand, the theoretical supposition is justifiable, that many of these abnormalities will take place in an asymmetrical way, and will disturb the symmetry of the foundation of the spine and, therefore, produce spinal curvatures, partly directly, in a mechanical way, partly indirectly, by compelling the body to compensation. There are already anatomical proofs that spinal deformities with the typical lateral and rotatory components can result from the above-mentioned conditions. Böhm does not claim that these congenital abnormalities represent any exclusive cause of curvature, but believes that they constitute a not uncommon cause.—*Boston Medical and Surgical Journal.*

Gastrotomy.—Riccardo Petrucci gives us the following conclusions as to the usefulness of gastrotomy in cases of stricture and tumors of the esophagus. Gastrotomy is easy of execution, is not a severe operation, and produces a permanent alimentary fistula, which gives no visible external deformity, and should not be abandoned. Whenever there exists an obstacle to the passage of food through the esophagus, whether from stricture or tumor, the operation is indicated. It not only keeps the patient from starving, but lessens his local pain from contact of the food with a neoplasm. It prolongs life and stops hunger and vomiting. The results are best when the operation is done as soon as the diagnosis is made. The fistula must be permanent, as small as possible and as high up as convenient, with folds of mucous membrane that close the orifice. The operation should be completed at a single sitting. The post-operative care is important. The daily diet must be supervised and the fistula kept open with sounds of suitable size, not becoming contracted at the point of entrance.—*Il Policlinico.*

Septic Awakening by Chloroform General Anesthesia.—J. B. Bloom describes several cases of this nature. One patient was a woman on whom a uterine curettage was performed for a condition that was not septic. The urine was normal. After the operative interference, which was not followed by any rise in temperature, a marked condition of genitourinary sepsis was awakened. This continued for quite a time, long after apparent convalesence had been established. The patient was advised to drink plentifully of water for the purpose of diluting the infection. No evidence of this former infection exists at the present writing, a period of very nearly two years having passed. The writer next describes two cases of appendiceal infection, both of virulent type. The first patient was a boy sixteen years old, in whom no septic condition could be found before operation. Afterwards, however, genitourinary sepsis was awakened and continued long after every evidence in the local wound, which was treated by the open method, was healthy. Recovery took place. In the second case of appendical infection, although the urine on admission showed nothing alarming, the patient died at the end of the third day after operation of convulsive seizures and urinary suppression, the abdominal symptoms being without pathological evidence. Pus and albumin were found in the greatest abundance in the urine. The last patient was a woman twenty-five years old, with fracture of both patellas. Both bones were operated upon at one sitting. Later the urine became purulent although before operation it was perfect in a general way. Pyelitis was followed by uremia, which ended in death after a confinement of four months. Within this time there was a period when her perfect recovery was anticipated. The writer thinks that cases of this kind are worthy of attention.—*New Orleans Medical and Surgical Journal.*

New York, October 13, 1906.

THE CLINICAL VALUE OF CRYOSCOPIC EXAMINATIONS.

IT is nearly ten years now that Koranyi of Budapest applied the determination of the freezing point (cryoscopy) to the study of pathological urine. Since then work has been constantly going on in various parts of the world with this method, and the results obtained seemed to vary so much that a great deal of skepticism has been expressed, both here and abroad, as to the actual clinical value of cryoscopy. We have had occasion more than once within these years to comment on the situation editorially. As has been and is the case with most of the newer laboratory methods, experience, tempered by judgment, and sustained by an increasing accumulation of statistics, has gradually crystallized opinion as to the value of cryoscopy, until to-day its limitations are quite well understood, while its advantages are fully appreciated.

After Koranyi's historic work came that of Claude and Balthazard; of Achard and Castaigne, of Bernard, of Casper and Richter, of Rovsing and of Kümmel—to mention only some of the more important investigators in this interesting field. But little of importance has been published in this country on cryoscopy during the past few years, if we except the practical and thorough paper of Dr. A. A. Berg of this city.

As the subject developed under the influence of these researches, the students of cryoscopy and its clinical applications came to be divided into two camps. On the one hand there were men who, like Claude and Balthazard, believed that cryoscopy was by far the most important method of determining the renal function, and that by simple calculations it was possible to determine even the relative amounts of certain constituents from the freezing point of the urine. On the other hand, there were the skeptics, led by Rovsing, who accumulated a mass of material to prove the fallacies of the method and its utter worthlessness, save in certain limited circumstances.

The last word on the subject has, of course, not yet been spoken, nor will it be for some years to come; and yet, in the recent study of functional diagnostic methods by Kümmel (*Berliner klinische Wochenschrift*, July 2 and 16, 1906), we find such an impressive array of facts and figures collected by that well-known surgeon in the course of six years, and based upon 404 operative cases of kidney lesions, with 1,000 or more cryoscopic examinations, that we think it worth while to present them here as probably the best solution of this important problem which has yet been offered.

Kümmel concludes from his experience that cryoscopic determinations made by beginners are worthless. It takes a great deal of experience to eliminate the sources of technical error. Cryoscopy of the combined urines of both kidneys is of no practical value, as the freezing point varies so widely under normal conditions. Cryoscopy of each separate kidney is valuable, as the freezing point of the diseased kidney is constantly higher than that of the healthy one. The freezing point of the blood is constant, and therefore a much more trustworthy criterion. Normally the blood freezes at 0.56°C., with normal variations up to 0.57°. If the freezing point is lower than that, the kidneys are not eliminating the metabolic products fast enough, and are probably diseased. If the freezing point of blood reaches — 0.60°C. nephrectomy is a risky operation, as the two kidneys combined do not excrete sufficiently well. If the freezing point is still lower, the operation is absolutely contraindicated.

Of the 404 operations by Kümmel, 189 were nephrectomies, 133 nephrotomies, 6 resections (partial) of renal tissue, 45 nephropexies, 11 decapsulations, 12 incisions of paranephritic abscesses, and 8 plastic operations on the ureter. The total mortality was 12.6 per cent. There was, however, a marked reduction in the mortality in the cases of operation after the introduction of cryoscopic examinations, as compared with the mortality of the preceding years. Thus, in 140 nephrectomies performed after cryoscopy there was not a single death; on the other hand, 6 deaths due to insufficiency of renal function, or to the absence of a second kidney, were recorded among the 41 nephrectomies which were done before the introduction of cryoscopy and ureteral catheterization.

There can hardly be any question, after such convincing proofs have been submitted, that cryoscopy, especially cryoscopy of the blood and of the urine of each kidney separately obtained, is of the utmost value as a diagnostic and prognostic aid in renal surgery. By this method, combined with other modern modes of examining the condition of the kidneys, the surgeon can be very reasonably sure that the second kidney is present and that it secretes enough urine to allow the patient to survive the operation. The limitations of the method are now well defined, and if the surgeon bears them in mind, and does not rely on cryoscopy to the exclusion of other diagnostic methods, he will not be disappointed in the results of the freezing-point determinations.

MATERNAL TRANSMISSION OF IMMUNITY TO DIPHTHERIA-TOXIN.

ALTHOUGH an admirable and promising beginning has been made in the study of the important question of immunity, from both the scientific and the practical standpoints, there are many phases of this most intricate and involved subject, some even of an elementary character, that yet require to be cleared. Exactly as susceptibility to infection, and even to intoxication, varies greatly in different individuals—and perhaps in the same individual at dif-

ferent times—and with respect to different infectious and toxic agents, so also are there wide variations in the matter of immunity, whether natural or artificial, inherent or acquired. The subject is of especial significance in connection with the standardization of serums for prophylactic and therapeutic purposes. Some valuable observations on this point are recorded in a recent bulletin issued by the United States Public Health and Marine-Hospital Service.*

For economic reasons it was thought that guinea-pigs that had been used for testing diphtheria-antitoxin, or for determining the strength of diphtheria-toxin, and had fully recovered, might be used also for breeding purposes; but, as a precautionary measure, it was decided to test the young of a number of such used and recovered animals, in order to see if they exhibited resistance to the action of diphtheria-toxin. If these animals proved resistant, tests of serum made on them must yield misleading results; while, if the animals exhibited merely average susceptibility, a great saving would be made in the purchase of animals for testing purposes. It had already been shown that guinea-pigs treated with a toxin-antitoxin mixture, or with horse-serum alone, transmit to their offspring a hypersusceptibility to injections of horse-serum, normal or antitoxic. Such young animals should, therefore, not be injected with serum for the purpose of determining the absence of bacterial and toxic contamination. As a result of the experiments undertaken, it was found that 7 of 14 female guinea-pigs, treated with a single injection of toxin or toxin-antitoxin mixture, transmitted to their offspring immunity sufficient to protect them from the effects of full lethal doses; and of 24 young animals 13 were resistant to full lethal doses. Of 10 mothers treated with toxin-antitoxin mixture, 7 transmitted immunity to their offspring, while no mother that received injections of toxin alone transmitted such immunity. Of 12 mothers treated with a single injection of toxin or toxin-antitoxin mixture, 6 transmitted to their offspring resistance to minimum lethal doses. Of 8 mothers that received toxin-antitoxin mixture, 6 transmitted to their young immunity to minimum lethal doses. Of 21 young animals 11 were resistant to doses of toxin fatal for control animals. No mother that received injections of toxin alone transmitted such immunity. In cases in which immunity was transmitted to the offspring all of the litter were immune to about the same degree. The fact that immunity was not transmitted by all of the mothers treated with toxin-antitoxin mixture may be due to the fact that some of the animals produce more antitoxin than others.

It was found, further, that the offspring of mothers treated by repeated injections of toxin-antitoxin mixture exhibited a marked resistance to full lethal doses of toxin. The evidence indicates that immunity produced by the injection of large amounts of antitoxin alone is not as lasting as that produced by small amounts in conjunction with small amounts of toxin. It was demonstrated that the resistance to diphtheria-toxin is not transmitted to the second generation.

An attempt to immunize female guinea-pigs by repeated small injections of diphtheria-toxin was unsuccessful, hypersusceptibility rather than resistance being thus established. A final series of experiments showed that a mother can transmit to the same offspring both immunity to diphtheria-toxin and hypersusceptibility to horse-serum. For this reason no female guinea-pig that has previously received injections of toxin-antitoxin mixture should be employed for breeding animals to be used in testing diphtheria-antitoxin. The transmitted immunity would yield misleading results, while the hypersusceptibility to the action of horse-serum would falsely indicate the presence of bacterial or toxic impurities in the tested antitoxin.

*Hygienic Laboratory, Bulletin No. 30, August, 1906. I Maternal Transmission of Immunity to Diphtheria-toxin. II. Maternal Transmission of Immunity to Diphtheria-toxin and Hypersusceptibility to Horse-serum in the Same Animal; by John F. Anderson.

THE RELATION OF FERTILITY TO SOCIAL STATUS.

It has been remarked, oftentimes with much alarm, that the birth rate is on the decline, particularly among those classes of the population in which an increase is most desirable. In France this fact has been accepted as a national calamity in the handling of which the government has taken a part. Other countries have also taken up this question, and one in which considerable attention has been devoted to the subject is England. In order to determine to what extent the decrease in the number of children in English families is differential, Heron, in a pamphlet issued by the Draper's Company of London (Dulau & Co., London, 1906), has made a careful study of the census and birth statistics for the past fifty years. His particular aim was to find out whether this reduced fertility of English wives was associated with conditions of poverty, disease, and generally unhealthy and improvident surroundings.

It is quite generally acknowledged that the working classes contribute the largest relative number to the population, notwithstanding the high infant mortality among them, and the present investigation again demonstrates that there is a close relationship between social status and the birth rate. "In districts where there is overcrowding, where there is a superabundance of the lowest types of labor, where it is needful to employ many young children in order to earn daily bread for the family, where infantile mortality is greatest, there the wives of productive age have the most children. Where there is more culture and education, as shown by a higher proportion of professional men, where there is more leisure and comfort, as shown by a higher percentage of domestic servants, there the birth rate is least." In such words the writer describes conditions which are duplicated here as well as in all other large cities, and as the ratio between inferior social status and high birth rate has practically doubled during the last fifty years in London, it is quite clear that the reduction in the size of the families has begun at the wrong end of the social scale and is increasing the wrong way.

Among the reasons adduced for this state of affairs, the postponement of marriage among the higher classes has often been referred to as an important factor, but according to Heron's figures

this does not hold at the present day, and the marked increase in the correlations between low social status and high birth rate must be due to other causes. The writer presents merely a statistical report, and ventures to present neither causes nor remedies. His report, however, points out certain distinct sources of national deterioration which are active in other countries as well as in England, and which before long must be considered by the statesman as well as the social reformer, and not, as hitherto, by the physician alone.

Consistency.

A short time ago, after the sudden conversion of the editor of the *Journal of the American Medical Association,* this gentleman, in his endeavor to kill off the independent medical journals, established the rule that none should be regarded as "ethical" which admitted to its advertising pages any proprietary remedy of which he disapproved. A full list of these tabooed preparations has never, to our knowledge, been published, but several have been mentioned from time to time as especially worthy of condemnation; the Medical Record has been held up to public scorn because it has admitted some of them to its advertising pages, and the physicians of the country have been urged to have nothing to do, either as contributors or subscribers, with any journals in which these preparations are advertised. There is a most readable monthly journal published in Chicago, *The Clinical Review,* which, like all the independent medical journals of the country, as well as many of the official organs of the State societies, accepts the advertisements of a number of proprietary remedies anathematized by the journal of the Association; in the current issue of the *Review* we have counted eleven of these preparations, among them the very particular *bête noir* of the editor of the Association *Journal.* There is nothing especially worthy of remark in this fact, but what is perhaps peculiar is that the list of collaborators of this "unethical" journal contains the names of several officers of the Association. Among them, to mention only three, we find M. L. Harris, Secretary of the Board of Trustees under whose direction the *Journal of the American Medical Association* is edited; Frank Billings, Treasurer of the Association and the vociferous foe of all nonpharmacopeial remedies; and William J. Mayo, President of the Association. We have no fault to find with this; the names of these gentlemen and of many others prominent in the Association are printed conspicuously on the front cover of *The Clinical Review,* and the journal is worthy of their support and approval. But some who do not know the true inwardness of this so-called reform may wonder at the inconsistency of those high in authority and may not be able to understand why one particular journal should be selected for reprobation for doing something which these officials of the Association, with what appears to be cynical indifference, publicly approve and sanction in the case of other journals. We say "other journals" advisedly, for *The Clinical Review* is not the only periodical, carrying "unethical" advertisements, which is edited and supported by officers of the Association.

The Effect of the Roentgen Rays on Growth.

It does not seem strange that an agent which has come into such universal use as a diagnostic and curative measure should be subjected to inquisitorial processes, for that is apparently the fate of popularity. Of the ability of these rays to cause burns there is little doubt, although with improvements in the tubes the frequency of *x*-ray burns is declining. Atrophy of the essential reproductive organs has also been ascribed to their employment, and it is moreover claimed that growth may be stunted. Försterling (ref. in the *Centralblatt für Kinderheilkunde,* September, 1906) has made some experiments with reference to the latter phenomenon and found a distinct inhibition of growth in various young animals when these were subjected to *x*-ray exposures of even ten minutes' duration, and the same effect was noted on the buds of different trees. These exposures were less than those ordinarily used for therapeutic purposes, but seemed to be accompanied in every instance by a well-marked effect. The latter was less, however, in older animals. The writer thinks we should, therefore, endeavor to restrict the use of this therapeutic measure in small children to cases of malignant neoplasms and lymphatic leukemia. When it is found necessary to apply the rays, all other portions of the body should be amply protected and the exposures should be limited in time and not repeated at too frequent intervals, in order to avoid a cumulative effect. Unfortunately we are not acquainted with the minimum dose of this agent by which a deleterious effect may be produced, and not until a device for measuring the rays is discovered can a solution of this difficulty be hoped for.

"Hyperovarie."

We often meet with a type of women in whom the sexual development, both mental and physical, becomes well marked at a comparatively early age. Menstruation is abundant and metrorrhagia is a frequent complication, but when there is any disturbance of the genital organs of a local character, amenorrhea appears. These girls are apparently well nourished, they are well developed in body, but in the course of time they become markedly anemic. Neuroses of various kinds are apt to be present, and the urine contains phosphates and nitrogenous elements. Women of this type may be very prolific, and the condition described is denominated by Dalche "hyperovarie." It forms a striking contrast to the state characterized by ovarian insufficiency in which development is backward, puberty appears late, and menstruation is scanty, unless there is, in addition, some disease of the internal genital apparatus. The skin is pale and clammy, and the appearance of the patient reminds one of myxedema; the urine contains a diminished amount of nitrogen and phosphates. Such women are usually sterile. Of the two contrasting types, the latter is the more frequent, but the former is now very apt to be found among women of the large cities. One of the important facts noted by Dalche is that many cases of virginal metrorrhagia of unknown origin are probably dependent upon this overdevelopment of the ovarian tissues, with its accompanying excess of ovarian secretion. The treatment should be symptomatic, and during the intervals between the periods vasoconstrictors and sedatives are indicated.

The Medical Host.—A French paper says that there are 228,234 medical men in the world. Of these there are in Europe 162,333, distributed as follows: In England, 34,967; in Germany, 22,518; in Russia, 21,489; in France, 20,348, and in Italy, 18,245. In England the proportion of doctors is 78 to 100,000 of the population. In France it is 51, and in Turkey, 18. In Brussels it is 241, in Madrid, 209, in Budapest, 198, in Christiania, 181, in Vienna, 140, in Berlin, 132, in London, 128, in Athens, 123, and in Paris, 111.

News of the Week.

Yellow Fever in Cuba.—Since September 1 six cases of yellow fever with two deaths have been reported in Havana, all occurring in the poorer parts of the city. The total number of cases in Havana thus far this year has been something over twenty. The deaths have numbered five. Outside of Havana there have been only eight cases since December. The infection is attributed to Spanish immigrants from South American ports. The facilities of the American Army are being utilized in the work of sanitation and the city of Havana is to be given a thorough inspection and cleaning.

More Meat Inspectors Needed.—The Bureau of Animal Industry has called on the Civil Service Commission for more eligibles for appointment as meat inspectors and veterinary surgeons, of which about 300 additional are needed to carry out the provisions of the meat inspection law. Examinations for these positions will be held in various cities throughout the country on October 17.

Value of Tent Colonies.—The Illinois State Board of Charities in its quarterly bulletin speaks of the beneficial results of the tent colonies at the various State insane hospitals for consumptive patients. The tent colony, for instance, at the Illinois Hospital for the Insane at Bartonville shows a per capita cost of only $50 per year.

Addition to Washington Park Hospital, Chicago.—Plans have been prepared for a three-story addition to the institution, to be built on a lot 50 feet by 150 feet, adjoining the hospital.

Opening of the New Pavilion at St. Luke's Hospital.—The Margaret J. Plant pavilion for private patients, connected with St. Luke's Hospital, New York City, will be opened at 3 o'clock P.M. on St. Luke's Day, October 18. The building, which is the gift of Mrs. Plant, has just been completed at a cost of $500,000.

Reception to Columbia Professors.—The faculty of Columbia University last Saturday held a reception for the fourteen new professors who took up their work with the beginning of the present academic year. The new members of the medical faculty are Dr. Frank W. Jackson, professor of clinical medicine, and Dr. John Henry Larkin, adjunct professor of pathological anatomy.

Dinner to Sir William Perkin.—Sir William Henry Perkin, the pioneer in the field of coaltar chemistry, was the guest of honor at a banquet at Delmonico's, given last week by four hundred chemists and manufacturers of chemical products. Sir William was presented with the first cast of a gold medal to be known as the Perkin medal and to be awarded each year to some American chemist distinguishing himself in the field of research. A silver tea service was also presented to Sir William.

Visit of Viennese Surgeons.—Dr. Ernst Wertheim, Professor of Gynecology in the University of Vienna, and Dr. Robert Mann, a prominent obstetrician of the same city, who arrived in this country on October 3, are visiting various Eastern and Southern cities for the purpose of inspecting the surgical clinics and of demonstrating European methods. They will return to New York later in the month as the guests of Dr. Sidney D. Jacobson and will operate in several of the hospitals in this city.

Dr. Horatio C. Wood has resigned the chair of materia medica, pharmacy, and general therapeutics in the University of Pennsylvania on account of ill health, and has been elected emeritus professor.

Dr. J. L. Amster of this city was thrown from his carriage last Sunday by a collision with a trolley car, and received serious injuries, including a fracture of the humerus at the shoulder and fracture of several ribs.

Dr. Neisser of Breslau has secured from the German Government a grant of 100,000 marks for the purpose of continuing his researches on the etiology of syphilis in Batavia. Neisser's previous investigations, carried on in 1903 and 1904 in Breslau and in 1905 in Batavia, were conducted entirely at his own expense.

Honors for Major Paul F. Straub.—President Roosevelt on October 6 conferred upon Major Paul F. Straub of the United States Army Medical Corps a medal of honor for gallant bravery in face of the enemy. On December 21, 1899, Major Straub, whose home is at Mount Pleasant, Ia., but who was surgeon of the 36th Volunteer Infantry, commanded by Brig.-Gen. J. Franklin Bell, rode in the face of the enemy's fire at Alos Zambales, Island of Luzon, and carried a wounded United States soldier to a place of safety. For this act of bravery he was commended at the time by Gen. Bell.

In Honor of Schaudinn.—In commemoration of the services to humanity of the late Fritz Schaudinn, a fund has been collected for the purpose of awarding biennially on the day of his death a medal, to be given for discoveries in the domain of microbiology. The award will be made under the auspices of the Institut für Schiffs und Tropenkrankheiten in Hamburg, with which Schaudinn was connected.

The Harvey Society of New York announces its second course of lectures, which will be given at the Academy of Medicine on Saturday evenings at 8:30 P.M. during the coming winter. The lectures are open to the public, and all interested are cordially invited to attend. The program for the year is as follows: October 20, A. E. Wright, London, "Therapeutic Inoculation with Bacterial Vaccines"; November 3, C. A. Herter, New York, "The Common Bacterial Infections of the Digestive Tract and the Intoxications Arising from Them"; November 17, W. T. Porter, Boston, "Vasomotor Reflexes"; December 1, J. G. Adami, Montreal, "The Myelins and Potential Fluid Crystals of the Body"; December 15, S. J. Meltzer, New York, "The Factors of Safety in Animal Structure and Animal Economy"; January 12, F. G. Benedict, Middletown, Conn., "Metabolism During Fasting"; January 26, E. B. Wilson, New York, "Recent Studies of Heredity"; February 9, G. S. Huntington, New York, "The Genetic Interpretation of Variations in the Genitourinary Tract"; February 23, W. T. Councilman, Boston, "The Relation of Certain Leucocytes to Infectious Diseases"; March 9, Friedrich Müller, Munich, "Neuroses of the Heart."

Wesley M. Carpenter Lecture. — This annual lecture will be delivered at the Academy of Medicine on October 18 by Dr. Harvey Cushing of Baltimore. The subject will be "A Discussion of Some Early and Some Late Complications of Cranial Injuries, Based Upon the Histories of Three Illustrative Cases." The lecture will be illustrated by photographs and diagrams.

Ontario (Can.) Provincial Board of Health.—The Ontario Cabinet has appointed the following as members of the Provincial Board of Health, to succeed those whose term of office expired last month: Dr. Charles Sheard of Toronto, Dr. Milton Ira Beeman of Newburgh, Dr. John William Scott McCullough of Alliston, Dr. Charles B. Coughlin of Peterborough, Dr. William J. Robinson of Guelph, and Dr. William R. Hall of Chatham. The term of office is three years.

Conference of New Jersey Boards of Health.—The first annual conference of the New Jersey State and local boards of health, as authorized by the act of April 19, 1906, will be held in the State House, Trenton, on October 19 and 20, 1906. Each local board of health is authorized to appoint one of its members or officers as a delegate to attend the conference. The conference will be opened by Dr. C. F. Brackett, President of the State Board of Health.

"Gaillard's Southern Medicine."—Dr. W. E. Fitch, owner and editor of *Gaillard's Southern Medicine,* has removed to New York City and in future the journal will be published simultaneously in this city and in Savannah, Ga.

Cost of Medical Study in England.—According to a recently published estimate, the expenses of the medical student in London may be figured about as follows: On entering one of the large London medical schools the bare fees will amount to £30 per annum, with an addition for the first years of £20 as entrance fee—that is to say, £170 to cover the five years. To this must be added the fees for certain additional and necessary practical classes and material, entailing an extra cost of perhaps 12 or 15 guineas. Subscription to the students' club will absorb another 15 guineas, and books, instruments, etc., say, £30 more. When examination fees, say 40 guineas, are added, and the official register fee, £5, we get roughly £280; pocket money and lunch in town mean quite another £25 or £30 annually, while putting clothes, board, lodging, etc., at £85 to £100 a year, we reach a total of £850 to £900, if the student gets through in the five years.

Overlying of Infants.—At a recent inquest held in London in the case of an infant suffocated while in bed with its parents, the coroner stated that about 2,000 infants annually lost their lives in this way in England, there being in the neighborhood of 600 deaths from this cause in London alone.

Prize for Trachoma Investigation.—The Hungarian Minister of the Interior has announced a royal international prize of 1,000 crowns for the best work on the etiology of trachoma. It is required that competitors present an original contribution which represents progress of value. Papers may be written in Hungarian, German, French, or English, and must be in the hands of the jury before December 31, 1908. Communications should be addressed to Ofen Pest, I., Var, Belügyministerium. Papers that have been published will be eligible, providing that they have not appeared before January 1, 1907. The prize will be awarded at the XVI International Medical Congress in September, 1909.

Iowa State Association of Railway Surgeons.—At the recent meeting of this Association officers were elected as follows: *President,* Dr. S. A. Spillman of Ottumwa; *Vice-President,* Dr. E. N. King of Muscatine; *Secretary,* Dr. A. B. Deering of Boone; *Treasurer,* Dr. E. C. McMell of Delmar.

Santa Fe Railway Medical and Surgical Society.—The election of officers for this society, held at the third annual convention on September 29, resulted as follows: *President,* Dr. George W. Miel of Denver; *First Vice-President,* Dr. Charles Dunning of Arkansas City, Kan.; *Second Vice-President,* Dr. George C. Highsmith of Carrrolton, Mo.; *Third Vice-President,* Dr. J. E. Lively of Blackwell, Okla.; *Fourth Vice-President,* Dr. J. J. Shuler of Raton, N. M.; *Secretary,* Dr. W. A. Uehren of Topeka, Kan.; *Treasurer,* Dr. J. D. Freeman of Topeka, Kan.

The Late Dr. Otis.—At a meeting of the Medical Board of St. Mark's Hospital, held October 2, 1906, the following resolutions were adopted:

Whereas, Death has removed from among us the beloved Vice-President of our Board, Dr. William K. Otis, long and favorably known and respected among us, therefore be it

Resolved, That we deeply regret the loss we have sustained in the demise of one of the pioneers in the genitourinary surgery in this country, and who was loved by everyone with whom he came in contact;

Resolved, That we extend our deepest sympathy to the bereaved family of the deceased, and that a copy of these resolutions be spread in full upon the Minutes of the Medical Board and be published in the medical papers.

Signed: Carl Beck, President of St. Mark's Hospital; Reynold Webb Wilcox, President of the Medical Board; Ignatz Morvay Kottenberg, Secretary of the Medical Board.

Obituary Notes.—Dr. Silas B. Dickerman of Abington, Mass., died on October 1, at the age of fifty-seven years. He was born in London, N. H., was graduated from the Hahnemann Medical College of Philadelphia in 1872, and had practised in Abington ever since.

Dr. Francis J. McQueeny of Boston, Mass., died suddenly on October 2, at the age of forty-seven years. He received his medical degree from the Harvard Medical School in 1890, and two years later began to practise in Boston.

Dr. Frederick Crang of Forest Grove, Ore., died on September 25. He was born in England in 1822, and practised in London until 1856, when he came to America. After practising in the East, he went to Oregon in 1875, and had since resided at Astoria and Forest Grove.

Dr. Walter W. Routh, former health commissioner of Duluth, Minn., died on September 28, at Pasadena, Cal. Dr. Routh was fifty years of age and had practised in Duluth since 1891.

Dr. Walter Clark Jackson of Montgomery, Ala., died on September 27 at the age of eighty years. He was well known throughout the South as an expert in yellow fever, and had been treasurer of the Alabama State Medical Association continuously for a period of twenty years.

Dr. C. E. Barnes of Burlington, Ia., died on September 30, after a long illness. He was born in Ohio in 1861 and received his medical education at Rush Medical College in Chicago. He began practice in Burlington in 1883, and was city physician from 1887 to 1892. Ill health compelled him to give up active work five years ago.

Dr. Edward Bliss Foote, formerly of this city, died on October 5 at his country home at Larchmont, at the age of eighty-seven years. He was the author of numerous books on medicine and on popular medical subjects, and for many years was the editor of the *Health Monthly.* Several years ago he gave up active work and retired to his country home in Larchmont. He is survived by two sons, Dr. Ed-

ward B. Foote and Dr. Hubert P. Foote of this city.

Dr. Emil Wilhelm Hoeber of this city died on October 5, after a short illness. He was born in Carlsruhe, Germany, in 1833, but came to this country in 1858 and was graduated in medicine from the New York University Medical School. He served as coroner of this county during Mayor Strong's administration.

Dr. Minerva M. Greenaway of Toronto, Can., died of typhoid fever on September 28. She was graduated from the Ontario Medical College for Women in 1899, and was for a time connected with the Western Hospital of Philadelphia. She began to practise in Toronto two years ago.

Correspondence.

THE FIRST PHYSICIAN TO TREAD AMERICAN SOIL.

To the Editor of the Medical Record:

Sir:—Permit me to correct a slight mistake in your notice of the sketch on Dr. Diego Alvarez Chanca, published by me in *Janus,* in which you say that he was the first member of the medical profession to land on the shores of America. With Christopher Columbus, on his first voyage of discovery to America, there were two members of our profession, two ship surgeons or *fisicos,* as they were then called in Spain, one named Maese Alonso and the other Maese Juan. The first came over with Columbus on board the caravel *Santa Maria* and returned with him to Spain, while the second, having been put in charge of caring for the health of the thirty-eight men left by Columbus in the little fortress of La Navidad, in the Island of Hispaniola or Santo Domingo, was there massacred, together with all the rest of his companions, by the aborigines of that island commanded by the cacique Caonabo. All this is contained in my monograph on "The Medical History of Christopher Columbus," which is the first and only one existing on that subject, read by me before the First Pan-American Medical Congress, held at Washington, D. C., in 1893.

A. M. Fernandez de Ibarra, M.D.

2164 Fifth Avenue, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

"RETURN CASES" AT ISOLATION HOSPITALS—GOVERNMENT AND ANTIVIVISECTION; ROYAL COMMISSION—CONFERENCE ON PHTHISIS—DR. SAVAS IN LIVERPOOL—SUCCESS IN PRACTICE—DAMAGES FOR TYPHOID—OBITUARY.

London, September 21, 1906.

Another report has been made to the Asylums Board on cases of scarlet fever and diphtheria contracted from patients discharged from the Board's hospitals —"return cases," as they are called. Dr. F. M. Turner is the reporter, and his statistics extend over three years, embracing 1,000 consecutive cases at the Eastern Hospital. The conclusions are not just what the prevailing opinions would indicate. The contagiousness of the peeling stage of scarlet fever is described by the figures, and in this respect they support those adduced by Dr. Cameron in a previous report. On the other hand, they do not support Dr. Cameron's view that a great number of return cases are to be accounted for by coincidence. The report agrees with the previous one as to the influence of the time spent in hospital on infectivity. A stay of less than eight weeks or more than ten give a less proportion than that of the totals of eight to twelve weeks. The influence of nasal complication is reported on. Dr. Turner found 3.27 per cent. of uncomplicated cases caused infection on returning home; of nasal cases, 2.62 per cent.; of other complications, 1.54 per cent. But a different conclusion may be drawn from another table, which shows among cases discharged under eight weeks the returns rose to over 6.5 per cent.

"Return cases" sometimes give rise to complaints against the isolation hospitals. It is not unnatural that parents, having been compelled to send their children to these institutions, should be bitterly disappointed when they are brought back as cured and disinfected, if they should infect others. If the ubiquitous reporter scents such a case he at once proclaims the grievance, and the newspapers echo the "hospital scandal." Such an instance has just occurred at the Brentford Hospital and the papers have been repeating the usual cry. The management, they assert, must be to blame, and the difficulties of administering these institutions are quite ignored. The reporters' notion of "return cases" seems to be that the doctors, nurses, and managers must be to blame. In the case of Brentford, the Council met on Tuesday to consider the matter, and discharged two nurses and appointed a new superintendent, pending the election of a new matron. Thus a scapegoat has been found, but how far justice has been done does not appear, the proceedings of the committee to inquire and the Council not having been made public.

The Government has again bowed the knee before the threats of a band of noisy fanatics among its own supporters. This time it is the antivivisectionists whose screed has terrified the "big majority." Tuesday's *Gazette* announced a Royal Commission "to inquire into and report upon the practice of subjecting live animals to experiments, whether by vivisection or otherwise; and also to inquire into the law relating to that practice and its administration; and to report whether any, and if so, what, changes are desirable." So we must look forward to further agitation and the republication of charges by the antis under the name of "evidence," which, however often refuted, are positively repeated by interested agitators and believed by those weakminded people who accept as facts whatever the propagators of sensational stories may assert. Seats on the commission are assigned to Sir Wm. Church, Sir John McFadgean, Dr. W. H. Gaskell, Dr. Geo. Wilson, and Sir Job Collins. These gentlemen, assisted by a lieutenant-colonel, a permanent under-secretary of the Home Department, a couple of barristers, and a captain (as secretary), and presided over by Viscount Selby, speaker of the House of Commons from 1895 to 1905, may be expected to sift the statements submitted to them. The newspapers regard the medical members as advocates of experiment, and the others as condemning it in every case. The latter may well be led by the gentleman who has so often troubled the House and the public on the cruelty of muzzling dogs—canine comfort being with some of greater importance than the suppression of rabies.

Among the many ways in which the antis keep up their agitation, you may be amused to learn that on Saturday a memorial fountain was unveiled in the Battersea new recreation ground, declared open on that day by the Mayor, although not yet completed. The fountain, of red granite, is surmounted by a bronze model of a dog and an inscription in relief sets forth that the animal was a victim of vivisection, and calls on the men and women of England to demand that the practice of it shall cease. The cost is said to have been about £130, contributed by an International Anti Council. In a discussion on this subject a correspondent remarks that it is sad "to reflect on the many poor children who might have been made happy for a fortnight in the country with the money spent on this ridiculous memorial. But I forget; the health and happiness of several children is nothing when a dog's memory has to be considered."

The discussion in question has been going on for a couple of months in the Hertforshire *Mercury,* and has only been closed by the editor this week. It is a very superior example of the debates so largely got up by the fanatics, as two or three medical men have taken the trouble to refute some of the wilder statements reiteratd by the antis. Of course the two or three inevitable heterodox doctors also put in an appearance—Edward Berdoe, editor of the *Zoopsbritist,* and W. Hardwen of Gloucester. The clergy are also represented, and the angry and hysterical women. It is curious that so many antis fail to keep their temper in discussion. It is curious, too, how constantly they go off into side issues and irrelevant statements. Dr. Hardwen declared that Erasistratus disproved Galen's discovery about the arteries when another correspondent asked him to explain how Erasistratus managed to do this 400 years before Galen's discovery. A cleric who intervened with criticism of the Bible of the so-called higher sort is told by a lay disputant that he does not find the spectacle of a minister trying to explain away the inspiration of the Bible very edifying. Another quotes the saying as to not a sparrow falling, and is rebuked by a later letter with the remainder of the quotation, "ye are of more value than many sparrows." These specimens suffice to show the sort of discussion which has filled many columns in other papers as well as the one noticed. This one has, however, brought out a disclaimer from Sir F. Treves, who is being continually instanced by the antis as in favor of their contention. It appears that he has been driven to reprint as a leaflet a letter to the *Times* of April 9, and send it as a reply when his attention is called to these misrepresentations. In it he says his solitary utterance on the subject is in an address reported in the *Lancet,* November 5, 1898, in which he said he had found that operations upon the intestines of dogs were useless as a means of fitting the surgeon for operations on

the human bowel. He goes on to say: "Those who are familiar with the controversial methods of the antivivisection party will not be surprised that certain of my remarks have been cunningly isolated from the context and have been used (in advertisements, pamphlets, and speeches) to condemn all vivisection experiments as useless. . . . . No one is more keenly aware than I am of the great benefits conferred upon suffering humanity by certain researches carried out by means of vivisection."

One of the worst features of these newspaper polemics is the way in which the antis declare thousands of untold cruelties are continually going on, and quote figures including mere subcutaneous injections, describing them as torture. Then, too, some of them assert boldly that a vivisector must of necessity be callous to all suffering. Others simply repeat tales that have been refuted over and over again. Others indulge in simple vituperation and hysterical passion; others are contented to contradict their opponents, and, funnier still, not a few seize the occasion to recommend quack medicines as sufficient to eradicate disease. Now and then, as in this latest case, someone protests against the antis' "unfortunate habit of losing their tempers," or begs them not to "let their angry passion rise," but to "cool down with the weather."

The Lewisham Board of Guardians, finding their Union Infirmary overrun by cases of phthisis, have decided to convene a conference of the Metropolitan Boards to consider the advisability of applying for special legislative powers, with a view of placing consumptive cases in separate hospitals or institutions, to be provided by the Asylums Board or some other central authority. At present there are fifty cases in the Lewisham Infirmary in two wards, or on balconies or in tents in the open air. It is said a single union can scarcely deal effectively with the matter, as extra provision would only induce an invasion of outside cases.

On Monday Professor Dr. Savas of Athens, vice-president of the Greece Antimalarial League, was entertained at the Liverpool Hospital School. Dr. Ronald Ross detailed his investigations in Greece four months ago, and described the ravages wrought there by malaria. With a population of only two and a half millions, 250,000 cases, with 1,760 deaths a year, were sapping the vitality of the country. The successes achieved in Ismailia, Havana, and the Campagna proved the possibility of abolishing the disease by clearing the swamps, which were the breeding-places of the malaria gnats. This was the task before Greece.

The *Grand Magazine* is a monthly which I seldom see and which from a recent contribution medical practitioners will perhaps think beneath their notice. In it Dr. Snow ranges the causes of success in the profession in the following order of importance: Unscrupulousness, selfishness, hypocrisy, industry, and ability. He says no one with the merest vestige of a conscience should become a medical man, that benevolent instincts and sympathy should be sternly suppressed, that in country districts it is advisable to varnish your real sentiments with a cloak of religious hypocrisy. If Dr. Snow only wanted to be talked about, he has succeeded in a few quarters, where his article is denounced as a malicious libel. In other quarters he is simply regarded as beneath contempt. A few ask in mild surprise whether he is himself successful, and whether such success as he has achieved is due to the possession of the attractive qualities he attributes to the successful members of the profession. All seem to agree that whether he has been practising self-portraiture or not, he should not have contributed his picture to a popular magazine. But in this obtrusion of himself on the public he is not alone.

The late outbreak of typhoid fever at Basingstoke resulted in fifty actions for damages against the Borough Council, as the epidemic was traced to the water supply. The actions have now been settled by a payment of £1,650/15 without prejudice and with a denial of liability. A fresh source of water supply has been obtained.

On Saturday a printer was sentenced to three months' imprisonment for libel on a doctor. The judge characterized the libels as serious and thoroughly unjustifiable.

Mr. W. Spencer Watson, R.B. 1860, F.R.C.S. 1862, died on the 17th inst., aged seventy. He was for many years surgeon to the Central Ophthalmic Hospital and to the Throat Department of the Great North Central Hospital. He wrote a good deal on both specialties. His "Abscess and Tumors of the Orbit," 1870, was followed by a volume on "Diseases of the Nose and Accessory Cavities" which maintained a high place and in 1890 reached a second edition. "Anatomy and Diseases of the Lacrymal Passages" followed in 1892.

Mr. D. H. Goodsall, F.R.C.S., senior surgeon to the Metropolitan Hospital and to St. Mark's Hospital, died on the 14th inst. He was an alumnus of Bart's and qualified at the two colleges in 1870 and took the higher surgical diploma two years later. He contributed to *St. Bartholomew's Hospital Reports*, the *Transactions of the Medical Society*, and the *Lancet* various articles on rectal diseases and their surgical treatment. To the first-named he contributed "Twenty Cases of Foreign Bodies in the Rectum," in 1887, and he had an excellent practice in this branch of surgery. In 1892 he reported to the Medical Society two cases in which he opened the cecum for obstruction

Progress of Medical Science.

Boston Medical and Surgical Journal, September 27, 1906.

Diseases of the Bile Passages, Including the Liver, Gall-Bladder and Pancreas.—Papers on this topic are contributed by M. R. Richardson and E. G. Cutler. The former comments on the surprising number of unsuspected lesions found in the right upper quadrant of the abdomen. He reviews the present status of the gallstone question, and utters a caution against hasty and ill-considered operations in this region. Even when the diagnosis is plain, no surgeon has a right, he claims, to operate on the biliary tract unless he has had a large experience in general operating. He then passes to a discussion of the symptoms referable to gallstone at the usual sites of impaction, pointing out the great advantages of operating before the lining of the gall-bladder has become diseased. The great mortality of gall-bladder surgery occurs in cases of impaction in the hepatic or common duct, owing to the far-reaching changes of obstructive jaundice and the increased difficulties of dissection. The rule by which he has been guided and which he has rarely, if ever, had occasion to regret, is that when symptoms exist in the right upper quadrant which are of a chronic character, when the attacks of pain or distress continue, especially at irregular intervals, and when the attacks of pain in any form suggest the presence of gallstones, exploration is indicated, particularly when palliative measures have been employed in vain for a reasonable length of time. When later signs confirm the existence of gallstones, any measures other than surgical are unreasonable and ineffectual.

Dr. Cutler summarizes the symptoms of all these conditions: Pain, tenderness, fever and chills, vomiting, sweating, rapid pulse with increased tension during an acute attack, and perhaps diminished tension with mere inflammation of the ducts, jaundice (a very inconsistent symptom), tumor of the gall-bladder, bile in the urine (variable, with or without albuminuria) in the stools, (variable), and leucocytosis in suppurative complications. Differential diagnosis is called for from gastric ulcer, appendicitis, renal colic, pancreatitis, angina pectoris (in irregular cases), portal pylephlebitis, subdiaphragmatic abscess, and gastric crises of tabes. He says that the promotion of the free passage of bile to the intestine and the prevention of concentration and stagnation in the gall-bladder is thought to be favored by the giving of some of the soda salts, as the sulphate or phosphate, in doses of from 1 to 2 dr. daily. Oleate of soda in pill form has received the indorsement of Robson in cases that declined or were unfit for operation. The attempts to dissolve the gallstones *in situ* have not thus far been successful. Something may be accomplished in the way of prophylaxis by regulation of diet, prescribing regular exercise, the use of saline purgatives, and care of the general health; but after all the case is almost always sooner or later sure to come into the hands of the surgeon, and it is far wiser to call him in early as soon as the diagnosis is established and together to determine on the future course rather than to wait till some serious complication has arisen and the surgeon must work at a disadvantage.

New York Medical Journal, September 29, 1906.

Etiology of Uterine Fibroids.—D. H. Griffiths enumerates the clinical conditions under which fibroids of the uterus occur, suggesting that during the monthly congestion of the organ, one or more blood-vessels may have burst, owing to the inability of their delicate walls to sustain the increased pressure thus thrust upon them. The usual reparative processes following hemorrhages into tissue lead to the formation of a small bit of fibrous tissue. This acts as a foreign body, and more fibrous tissue forms around it and finally we have a fully-developed fibroid, large enough to be diagnosticated. It is possible that a subsequent decrease in size is due not to resorption of the mass but to a contraction of the fibrous tissue to the

smallest amount of space possible, just as any other piece of inflammatory fibrous tissue will contract. The contraction may also produce changes which usually follow when a part is not supplied with the necessary amount of blood.

Drugs in Diabetic Glycosuria.—A. C. Croftan enumerates the various drugs which at different times have been suggested for this malady. Concerning organotherapy he says that on theoretical grounds it should be efficacious in this disease, but however seductive the use of pancreas preparations or of combinations of pancreas with muscle or with liver or with salivary gland extract may appear, practically nothing of definite value has so far been observed from their administration. Pancreas is occasionally useful in the treatment of the steatorrhœa of diabetes, but it has no effect upon the glycosuria. The author has reported cases in which the boundary of tolerance seemed to be raised by the use of pancreas muscle extracts, but observations made subsequently in a larger number of cases have failed to support the first results. Liver extracts and brewer's yeast have all been used, but the optimistic claims advanced in the beginning have never been vindicated, although yeast often favorably influences the furunculosis of diabetes. Nevertheless, organotherapy appears to be a very hopeful field, and while nothing tangible has so far been accomplished, we may hope some day to discover an efficient organotherapeutic method of combating the disease. In regard to general tonics such as arsenic, quinine, etc., the author says he has never been able to observe from their use any effect on the general course of the disease or on the amount of sugar excreted though they may improve the anemic condition and possibly stimulate the nervous system to increased activity.

Pathological Physiology.—This branch of medical science includes, according to Byron Robinson, the field lying between normal physiology and pathological anatomy. It is the study of abnormal function. Its foundation stone is the diagnosis of functional deviation of abnormal visceral action. It presupposes a knowledge of normal physiology. It depends on laboratory methods for rational knowledge and practical application. On this basis the treatment of diseases consists in (1) the detection and removal of causes, (2) the regulation of visceral function by (a) fluids and (b) food, (3) habitat, (4) aeration, and (5) prophylaxis. The remainder of the paper is devoted to a detail of treatment under these respective headings. For visceral drainage by fluids, the author gives eight ounces of from one-fourth to one-half normal saline solution six times daily at two-hour intervals. Drainage by food is effected by cereals, vegetables, albuminoids (milk, eggs, buttermilk), and meats, the latter being limited, as they produce excessive uric acid formations. For a laxative, the author recommends the following tablet: Cascara, gr. 1-40; sodium bicarbonate, gr. 1; potassium bicarbonate, gr. 1-3; aloes, gr. 1-3, and magnesium sulphate, gr. 2. This combination is used as follows: One sixth to one tablet (or more as required to move the bowels freely once daily) is placed on the tongue and followed by eight ounces of water (better hot). Also at 10 A.M., 3 P.M., and at bedtime one-sixth to one tablet is placed on the tongue and followed by a glassful of any fluid. In the combined treatment one-third of the sodium chloride tablet (containing eleven grains) and one-sixth to three alkaline tablets are placed on the tongue together before each meal and at 10 A.M. 3 P.M., and bedtime, followed by a glass of fluid. The six glasses of fluid may be water, coffee, tea, milk, buttermilk, cream, eggnogg, in short any nourishment. This method of treatment furnishes alkaline bases (sodium, potassium, and ammonium) to combine with the free uric acid in the urine, producing perfectly soluble alkaline urates, and materially diminishing the insoluble free uric acid in the urine. Also the alkaline laxative and sodium chloride tablets increase the peristalsis, absorption, secretion, sensation of the tractus intestinalis, urinarius, vascularis, lymphaticus, genitalis, which aids secretions and evacuation.

Journal of the American Medical Association, October 6, 1906.

Rocky Mountain Spotted Fever.—H. T. Ricketts reports that he has succeeded by alternating inoculations of monkeys and guinea-pigs in perpetuating Rocky mountain fever, and in preserving the virus. He describes the symptoms in the animals experimented on, showing their identity as well as that of the pathological conditions with those observed in the human species. He has also tested the infectiousness of the various organs of the bodies of the animals. The animal was bled from the carotid to deprive it of all the blood possible, and then each organ was ground with sterile sand and suspended in a physiological salt solution. The emulsions of each were brought as nearly as possible to the same density, and 5 cubic centimeters of each were injected intraperitoneally into guinea-pigs, weighing from 350 to 550 grams. The greatest virulence seemed to be in the organs that naturally contained the most blood, such as the spleen, liver, and bone marrow. In the case of the bone marrow, however, he remarks that the difficulty of its preparation increased the chances of infection, which must be considered. The kidney, however, was quite as infectious as other organs, much richer in blood, which he suggests may be accounted for by an accumulation of microorganisms in it by reason of its excretory function. Ricketts has not heard of any authentic example of a second attack of spotted fever in man, hence, it seems probable that one attack renders the body immune. This was found by experiment to be the case in the monkey, and by reasonable analogy we may assume it to be so in man. He concludes his paper with an account of his observations of the life history of the *Dermacentor occidentalis*, which, in view of the suspicion attaching to the species as the carrier of the infection, is a matter of some importance. The observations were made under laboratory conditions, and he suggests that the various stages may not quite correspond in point of time, therefore, with those in the natural state. More complete observations will be published later.

Osteoplastic Resection of the Costal Arch to Reach the Vault of the Diaphragm.—Willy Meyer gives the history of two cases in which he employed resection of the costal arch, one of impermeable stricture of the esophagus, the other a case of sarcoma of the spleen in which it was impossible to reach the upper pole of the organ, tightly fastened in the vault of the diaphragm. In the second operation the seventh costal cartilage, representing the union of three, was divided close to its sternal attachment and the seventh, eighth, ninth, and tenth cartilages likewise, just in front of their union with the ribs. In cases of need, the ribs may be divided, further outward, including the fifth and sixth, and such modifications as are required can be made in the shape of the flap.

Tuberculosis of the Kidney.—A. D. Bevan calls attention to the frequency of the condition, to its diagnosis, especially by the *x*-rays, and examinations for the bacilli which he thinks pretty generally obviate the necessity of exploratory operations. He then points out that since in 90 per cent. of the cases the infection is through the circulation and is limited to one kidney, there is but one operation to consider and that is the removal of the diseased organ. He does not consider it necessary to remove with this the entire ureter, as its mucosa, though involved, usually recovers after the kidney is removed. Bevan states that he knows no more satisfactory results in the whole field of surgery than those obtained by early nephrectomy in the unilateral kidney tuberculosis.

Whole Milk versus Laboratory Milk.—A. McAllister points out that laboratory milk, understanding by the term every form of milk other than raw cow's silk or fresh cow's milk diluted and warmed to about 100° F., is in everything but its chemical composition, very far from being a duplicate of mother's milk. It lacks the living principle. The natural ideal substitute is fresh cow's milk, and drawn and handled with the care demanded by laboratory standards; cooled at once and kept cool, it possesses all the important vital constituents. Such certified milk can be supplied, he declares, if the public demands it.

The Lancet, September 22, 1906.

Successful Treatment of Thoracic Aneurysm Threatening to Rupture Externally.—The patient of E. E. Young was a man of 43 years. A large pulsating swelling existed in the neck and upper thorax from the lower border of the thyroid cartilage to the third rib. On its upper and anterior aspect was a smaller swelling about the size of a hen's egg. The patient was put to bed, kept absolutely quiet, and the head fixed by means of sand bags, no pillow being allowed. Diet was restricted for a few days. The iodide was begun in ten-grain doses and rapidly increased, so that by the end of three weeks the patient was taking

a dram three times daily with no ill effects. Collodion was painted over the swelling night and morning. In the course of ten days symptoms had considerably abated. At the end of six weeks he was allowed to sit up in bed, and in another month he left the hospital to resume work. There was no history of syphilis in the case.

Concussion of the Spine, with Some Remarks on Concussion in General.—The histories of six cases are given by E. M. Corner, who says that a distinction exists between concussion in general and that of the spine in particular. By the former he refers to cases in which shaking results from violence applied relatively at a distance from the part affected. In local concussion, as of the spine, the violence is applied close to the organ, the resulting shaking being not uniform or equable, but greatest near the site of the injury. With reference to theories of pathology the author prefers that of molecular disturbance and displacement. In slight shakings there is no gross anatomical lesion, but if there is greater violence exerted, there may be minute anatomical lacerations produced by the molecules, one upon another, and so, multiple hemorrhages. True concussion of the spine is a very rare injury, for the cord is tethered on both sides by the nerves and ligamentum denticulatum so that it cannot come into contact with the walls of the cavity in which it lies. In the case of the brain, it is anchored at its base, but its upper part can make considerable excursions. The *contrecoup* lesion of the brain does not have any parallel in the case of the cord. The author refers to one case in which fracture of the axis as determined by the *x*-ray produced a local spinal concussion. The same result followed a fracture of the fifth cervical vertebra. He also refers to three cases of what he calls marginal concussion. Whenever there has been a serious lesion of the cord, the segments immediately above and below the seat of the injury will be concussed. This concussion is frequently masked by the presence of a hemorrhage. He considers it quite possible to recognize the concussion which accompanies and is above a gross spinal injury, always provided it is not obscured by a hemorrhage.

Boric Acid and Appendicitis.—R. Harrison refers to the statement made with some authority that the frequency of appendicitis in recent years has been augmented by the large use of boric acid and other chemicals used as food preservatives. The usual symptoms referable to this cause are severe dyspepsia and flatulency. He has always thought, he says, that some mechanical disturbance connected with digestion would be eventually determined as playing an important part in the causation of appendical inflammations. He says it may be assumed that the appendix takes no part in the digestive or intestinal function and is not structurally or physiologically fitted for it; in fact, it would appear that any attempt to use it as a receptacle for either the natural or accidental contents of the canal may be the first step in the process which eventually ends in inflammation of this blind and rudimentary sac. Anything entering it, gaseous or otherwise, must be incapable of "moving on," and unless regurgitation haply and fortunately takes place the imprisoned contents are liable to undergo active bacterial decomposition with the evolution of foul and irritating gas. The initial lesion which probably renders appendicitis possible is the opening or blowing out of the appendical canal to such a degree as to render it accessible to the contents of the intestines as carried along by the ordinary and extraordinary means of propulsion technically known as peristaltic action. When this condition has thus been fairly well established the ease and even life of the appendix, not to say anything of the individual, are liable to become precarious. In this sense flatulent dyspepsia, however produced, may lead up to an appendicitis.

Stammering and Its Treatment.—R. A. Worthington divides the common forms of stammering into two main varieties. (1) A complete arrest before some initial letter. This form occurs in nearly ever case and is most common on the explosives. According to the hypothesis we have adopted the check is due to a delay in throwing in the vocal element on or just after the explosion. (2) An indefinite prolongation of an initial consonant. This occurs at friccatives (*f, l, s, etc.*) and nasal resonants, and is not so constant a feature as the first. A stammerer cured is not the same as a man who has never stammered. Without incessant watchfulness on his part he is certain to relapse. General principles of treatment may be summarized as follows: (1) Any local physical defect in any of the organs of speech should be remedied. (2) We should determine in what part of the mechanism the disturbance primarily arises and which of the phenomena are secondary. (3) The latter may be disregarded but the former call for exercises in the proper mode of breathing, and management of air supply. (4) We should endeavor to induce in the patient a constant habit of speech in which rhythmical pronunciation plays a prominent part.

British Medical Journal, September 22, 1906.

Treatment of Chronic X-Ray Dermatitis—I. H. Harris has been a sufferer from this lesion, his fingers being chiefly affected. He tried all sorts of remedies without any benefit. Eventually he dispensed with salves and resorted to very fine sandpaper, which he used at first daily and subsequently less often, with marked benefit. He had a couple of painful warts and small ulcers which would not heal and which caused excruciating pain. These were excised, and although the healing occupied three times the normal period, the eventual results were most gratifying.

Pulmonary Abscess Caused by a Tooth.—The patient of J. D. Davies was a young woman, complaining for seven months of pain in the right side of the chest, cough, and expectoration. All the symptoms pointed to tuberculosis. In a violent fit of coughing she raised, in a large discharge of pus, a second bicuspid tooth which had been extracted about the time her symptoms began and which must have been drawn into the glottis while she was under gas, lodging in one of the divisions of the right bronchus and causing abscess formation. Its expulsion relieved all symptoms.

Simulation of Mastoid Disease.—S. Paget reports two cases. One was that of a young woman, a hospital nurse, with a slight discharge from the left ear, with alleged severe pain over the mastoid. Her temperature began to rise every evening and operation was thought of, but it was found that while the temperature was 104° in the axilla, it was normal in the mouth. In ten days the temperature became steady, the patient ceased to complain of pain, and appeared in perfect health. The other case was also that of a nurse with symptoms similar to the above. She was known to be hysterical and a chloral habitué. On her admission to the hospital she had the appearance of a case of meningitis or cerebral abscess. It was not deemed prudent to leave her without operation, so the mastoid antrum was opened but no pus found. In the course of the next few weeks her condition became normal, but it was learned that a year later she was admitted with the same symptoms to another hospital, unable to walk or stand, hardly able to speak, and wearing spectacles not made of lenses but of plain glass.

The Significance of Some Enlargements of the Thyroid Gland.—A. F. Martin presents the following conclusions: (1) A call for increased functional activity is sufficient cause for simple enlargement of the thyroid gland. (2) Such a call is frequently given by the metabolism of the organism in connection with growth and development, with the performance of the uterine functions in the female, and with the chlorotic conditions of young girls. (3) The phases of enlargement of the thyroid included under the term "thyreocele" are a response to such an appeal from one or more of the above causes in an individual whose thyroid function is feebly performed. (4) As undue physiological activity is a potent cause for pathological change, so this simple hypertrophy, when necessitated for prolonged periods, lays the foundation of the pathogenesis of the degenerate cystic and adenomatous bronchocele. (5) There is often some influence exerted by heredity upon the thyroid function.

Berliner klinische Wochenschrift, September 17, 1906.

Toxic Nystagmus.—Weyl says that nystagmus has been observed in certain cerebral conditions such as meningitis, multiple sclerosis, Friedreich's disease, brain tumors, and cerebral injuries. It also occurs in about 5 per cent. of coal miners, and compositors, sometimes, though rarely, exhibit it. The author describes a form which he says has not yet been mentioned in the literature and which he terms toxic nystagmus. He was able to observe this condition in about 8 per cent. of a very large number of rabbits subjected to experiments in which poisoning was induced with phenol, cresol, and allied substances. The symptom was evoked on the administration on the average of one gram or less of the poison per kilogram of body weight, and usually appeared within forty minutes of the injection of the poison toxic agent. It lasted from a few minutes to over an hour. It is suggested that the constituents of coal tar may have something to do with the occurrence of nystagmus among miners.

Münchener medizinische Wochenschrift, September 18, 1906.

The Precipitate Reaction.—Fornet presents a preliminary communication on what he terms the precipitate reaction to distinguish it from the precipitin reaction. It

is a reaction depending on the presence of precipitinogens in the blood of typhoid patients and is intended to enable the diagnosis to be made at a time preceding the appearance of the Widal reaction. It is carried out by mixing the serum of the patient with the serum of a rabbit that has been immunized by repeated injections of typhoid bacilli. The precipitate obtained is slight and requires careful control tests, but is said to be sufficiently distinctive for practical use. The author has applied the test in six cases of typhoid fever and in each instance obtained a positive result before the Widal reaction appeared, while observations on other febrile disorders were negative. In one case the author has been able to obtain the reaction in the urine, and he expresses the hope that it will be found possible to use this as the routine material in diagnostic work. A further description of the technique is promised for a later paper.

An Instance of the Transmission of Measles to a Distance by a Third Person.—Siegert says that it is generally accepted that measles is transmitted only very rarely through third persons and then only through very short distances. He has been able to find one instance, however, in which the contagium was transported by a third person who visited a patient while in a hospital for another condition, and he describes a somewhat similar case occurring in his own practice. The patient was a child under hospital treatment for marasmus and it was infected with measles by its mother, who had a fifteen minutes' walk from her home to the hospital. Several other children were sick with measles in the patient's home. The attack was a perfectly typical one, the prodromes appearing on the eleventh day and the exanthem on the thirteenth day after the exposure.

Vaginal Celiotomy.—Dührssen rehearses the advantages of anterior colpoceliotomy, as he terms it, and inveighs against those who are slow to take up his plan of procedure. He lays particular stress on the value of his retroversion operation, which consists in a modified vesicofixation, a silkworm gut suture being passed through the vagina, vesical peritoneum, and uterus. This suture is removed at the end of six weeks. The author states that he has records of over one hundred normal labors that have taken place after this operation. Dührssen considers that no practitioner should allow one of his patients with retroflexion to be subjected to either the Alexander operation or a laparotomy, the objection to the first being its ineffectiveness, and to the second the unnecessary gravity of the operation. He then reviews the possibilities of the anterior vaginal incision in the treatment of other uterine and pelvic conditions, and asserts that the pelvic organs can be rendered just as accessible to sight and touch if his technique is followed as through a laparotomy incision. He has now carried out his operation in 1600 cases with a total mortality of 2 per cent., and he uses it in 80 per cent. of his gynecological cases in which the abdominal cavity must be opened.

Deutsche medizinische Wochenschrift, September 20, 1906.

The Occurrence of Metallic Mercury in the Human Body.—Schmidt describes the case of a young man of twenty-six years, who four years previously had had his right leg amputated, owing to injuries received in a railway accident. When seen by the author he presented on the anterior surface of the right thigh an infiltrated area about two by three inches in size. Several fistulous openings had perforated the skin over this area and were discharging a small amount of seropurulent secretion. The supposition was that a hypodermic needle might possibly have broken off at the time when the amputation was done and been retained in the tissues, but on making a radiograph the infiltrated area was seen to contain a very large number of minute spherical foreign bodies. The skin and underlying tissues in the region in question were excised, and on cutting into the mass the foreign bodies were found to be globules of metallic mercury varying in size from 1-3 mm. in diameter and aggregating about 0.5 gr. in weight. It was impossible to discover in what manner the mercury had entered the patient's body, for apparently he had never received mercurial medication either subcutaneously or in any other form. The author reaches the conclusion that although the patient denied syphilis he must have at some time been treated for this disease by means of hypodermic injections of some mercurial preparation.

The Radical Operation for Carcinoma of the Larynx.—Bruns reviews the history of this operation which has shown its greatest progress only within comparatively recent years. A series of 188 total extirpations of the larynx performed during the years from 1873 to 1894 were attended by a mortality of 44 per cent., 32 per cent. of recurrences, and only 12 per cent. of the patients remained cured for a year or more. Bruns found that 114 cases of thyrotomy performed since 1890 were attended by a mortality of only 9 per cent., 22 per cent. of recurrences, and a cure lasting a year or more in 48 per cent. This improvement he considers is due largely to the fact that the diagnosis is made earlier and that the laryngectomy is only partial instead of total. Bruns performs his own operations under scopolamine-morphine anesthesia supplemented by local anesthesia, and does not leave any tube in the trachea. He considers that the endolaryngeal operation advocated by some laryngologists is ill advised, and is of the opinion that the external operation is to be preferred in all cases.

Spinal Anesthesia in Gynecology and Obstetrics.—Baisch, who has employed this method in 150 cases, including forty laparotomies, says that the chief objections to it as ordinarily performed are the following: If the dosage selected is within the limits of absolute safety anesthesia is not always secured to the requisite degree. The after-effects in the form of headache and vomiting are sometimes so severe as to be a serious matter for the patient. The retention of consciousness is a distinct disadvantage, especially in laparotomies requiring the elevated pelvic position. By the technique employed in the author's clinic these objections are met satisfactorily, and he considers that the method deserves a permanent place as a routine procedure. In order to avoid the after-effects it is necessary to exercise a certain amount of discrimination in the selection of patients. Individuals having a tendency to headache or to gastric disturbances are not suitable subjects for lumbar anesthesia. It is to be hoped that the chemists will succeed in producing anesthetics for use in this way which shall be free from all undesirable effects. The combination of scopolmaine-morphine narcosis with spinal anesthesia obviates the other difficulties, for when given in combination in this way, none of the drugs require such heavy dosage as is necessary when they are used alone, while at the same time the patient is in a somnolent condition throughout the entire course of the operation. The technique is described in detail. The method is not suitable for obstetric practice, however, owing to the weakening of the abdominal musculature which it entails and the comparatively short duration of the anesthesia.

French and Italian Journals.

Infantile Nocturnal Incontinence Due to Urinary Hyperacidity.—G. Carrière and L. Caudron declare that the pathogenesis of essential infantile incontinence of urine is very complex. The causes of this condition which have been recognized are legion and one of the least known of them is urinary hyperacidity. The writers after extensive observation of cases of this nature emphasize as the cause of the condition an abnormal increase of urinary acidity. In order to combat this condition, they prescribe the internal administration of alkalines in the form of bicarbonate or phosphate of soda. It should be remembered that when liquids are cut off from the evening meal the urine, which is less abundant, will be richer in urinary acid. The function of elimination of the skin should be encouraged by means of dry friction or by alcoholic rubs, by massage, or by the various methods of hydrotherapy. The treatment should be sufficiently prolonged to prevent a recurrence. It seems to be difficult to give exact limits to the duration of the treatment by the alkalines, but it should continue in rather large doses for at least two months. Not until the amount of urinary acidity falls to less than two grams during the twenty-four hours that the doses should be diminished gradually. Speaking in general, the treatment should extend over an approximate period of from five to six months.—*Le Nord Médical,* July 15, 1906.

A Study of Macrosomia in Infants at Birth.—Achille Guglielimi has made a study of macrosomia from the records of the obstetric hospital of Milan, in which he found histories of some 250 cases. His conclusions are given us. Children that weigh more than 4,000 grams are not rare. The study of these children includes the periods of pregnancy, labor, and early life. The causes of overgrowth of the fetus are various: heredity, number of pregnancies of the mother, duration of pregnancy, life conditions of the mother during that time, health and occupation of the mother, length of the interval since last pregnancy, and sex of the fetus. Diagnosis of excessive size may be made during pregnancy from the history and examination of the patient. Usually the pelvis is roomy enough to permit of delivery, but a considerable number of instrumental deliveries are necessary, while the labor is apt to be tedious and inertia is frequent. The placenta as well as the child is larger than normal in these cases. There are more males than females among these children. During the first few days of life there is a marked decrease in weight of these children, and growth begins slowly and after a longer interval than in other cases. The prognosis for the mother is better than for the child.—*Annali di Ostetricia e Ginecologia,* May, 1906.

Book Reviews.

A Compend of Pharmacy. By F. E. Stewart, M.D., Ph.G., Charter Member of the American Therapeutic Society; Formerly Lecturer and Demonstrator of Materia Medica and Pharmacy, Jefferson Medical College, Medico-Chirurgical College, and Woman's Medical College of Pennsylvania, Philadelphia, etc. Based upon Prof. Joseph P. Remington's "Text-Book of Pharmacy" and the United States Pharmacopœia, Eighth Revision (1905). Sixth Edition, Revised and Enlarged. With a Very Complete Index and Table for Converting English Measures into Metric and the Reverse. Philadelphia: P. Blakiston's Son and Company, 1906.

This compend is intended for the student of pharmacy, but medical students will find in it much useful information presented in clear and concise form. It will make a capital adjunct to any text-book on Materia Medica, and is well calculated to help the student in preparing for an examination.

Grundriss der Orthopædischen Chirurgie, für Praktische Aerzte und Studierende. Von Max David, Berlin. Second Edition. Berlin: S. Karger, 1906.

This work was written to meet the necessity for a book containing the elements of orthopedics, which shall be practical and meet the requirements of the practitioner and medical student in this field of medicine. Only those methods have therefore been described which can be readily carried out by the practitioner, and theoretical descriptions have only been introduced in so far as they were deemed necessary to explain the manner of treatment. All the expensive apparatus which is to be found in the special hospital has been excluded, and the practicability of the simpler varieties and their successful use is urged upon the general practitioner. In the second edition certain changes have been made in accord with the progress of this branch, and some new material has been introduced. The illustrations are numerous, but many of them are poorly executed. There is one of a "Yury cast" which is particularly poor. The text of the work is clear and concise, and a great deal of information is crowded into the pages of the book.

Gastric Surgery. Being the Hunterian Lectures Delivered Before the Royal College of Physicians and Surgeons in 1906. By Herbert J. Paterson, M.A., M.B., B.C., F.R.C.S., etc. New York: William Wood and Company, 1906.

Although stated to be lectures, the subject matter of this little book is presented in such a form that it constitutes an excellent text-book on the subject indicated. One of the most important points made by the author is to be found in the preface, where he states that the results obtainable in gastric surgery are far better than one would be led to expect from the text-books. This is undoubtedly true, and the pessimism which exists particularly with reference to cancer of the stomach should be dispelled. Although the stomach is more frequently affected by this disease than any other organ of the body, gastrectomy is truly stated to be one of the most infrequent surgical operations. In its early stage this is a strictly localized disease, and as we are now possessed of fairly accurate methods of diagnosis, early operative removal should be more frequently instituted than has hitherto been the case. An appendix contains a complete description of gastrojejunostomy, which is very useful, and there are tables from which the author has drawn his conclusions as to the value of various gastric operations. The book can be recommended to the general practitioner as a useful review of the subject indicated on the title page, and since, unlike many others, it is international in the sense that it recognizes the work of others besides those of the writer's nationality, it will undoubtedly meet with a favorable reception.

An Essay on the General Treatment of Spinal Curvatures. By Heather Bigg, F.R.C.S. London: J. and A. Churchill, 1905.

This book is issued as an installment of a more comprehensive work by the same author, entitled "Deformities, Debilities and Deficiencies of the Spine," and consists of a statement or general review of the principles which underlie the successful treatment of these afflictions. From a perusal of the book it becomes evident that the treatment can be successful only if the author's methods are used, as he takes occasion to impress on the reader at various opportunities, and the book furnishes an example of the personal effort in medical literature which we do not remember to have seen equaled except perhaps by some of the German writers. The essential point in Bigg's treatment seems to consist of the wearing of a brace of his own devising during the day and a plaster corset or similar contrivance at night. A considerable portion of the book is taken up with a review of other methods of treatment, but none of these seems to compare in efficiency with the writer's, and the contentions of Sayre especially are very severely criticised. Bigg's book is strongly opinionated, which necessarily would point to a large personal experience in the specialty referred to, and a more concrete account of the many successes which he claims have resulted from his treatment would be expected. But after all the "scolding" only a solitary case is cited as an illustration of his many claims to distinction.

The Theory and Practice of Medicine. By Frederick T. Roberts, M.D., B.Sc., F.R.C.P., Fellow of University College; Emeritus Professor of Medicine and Clinical Medicine at University College; Consulting Physician to University College Hospital and to Brompton Hospital for Consumption and Diseases of the Chest; Ex-President of the Medical Society of London; Ex-Censor, Lumlerian Lecturer, and Harverian Orator at the Royal College of Physicians of London; Formerly Examiner in Medicine for the Conjoint Board, University of London, Victoria University, and Oxford University. In Two Volumes. Tenth Edition. London: H. K. Lewis, 1905.

The appearance of a new edition of this standard treatise will be welcomed by many practitioners who remember with pleasure and gratitude the help derived from the study of it in their early professional life. The editions formerly succeeded one another with the usual rapidity of a popular work, but the interval since the publication of the ninth edition has been so long that the present revision comes almost as a new book. Those familiar with the work from the beginning, however, will recognize in this modernized edition an old friend rejuvenated; all the charm of the old-time treatise, in which the author's personality was impressed on every page, is present in this new version, which is at the same time in its essential features thoroughly modern and up to date. It is a little weak, perhaps, in the sections on etiology and bacteriology. The remark in the chapter on Scarlet Fever, for example, that "possibly contagion may gain an entrance by defective drainage" is rather suggestive of the past; in treating of Smallpox more or less is said of the different bacterial forms that have been found, but the barest mention is made of the possibility of a protozoan parasite, and nothing whatever is said of the work of Councilman and others in this country along that line; and under Syphilis a couple of bacillary finds are noted, but no mention is made of the spirochete. The statement that among the personal factors promoting the occurrence of yellow fever is "exposure to night air and dews" has also a rather antiquated flavor, although the author cautiously admits that "the mosquito theory is said to fit in with well-recognized facts in connection with epidemics." These defects in an otherwise superb work render it unsuitable as a text-book for students, but detract little from its utility as a guide for the practitioner who values a work on medicine chiefly for its sections on diagnosis and treatment. In this respect it maintains all its former superiority. Here the writer's individuality is conspicuous and the reader has the benefit of the life-long experience of an acute and able practitioner. As the author says, the work embodies his personal experience and opinions in relation to a large number of subjects which he has had special opportunities of studying, and it is this which render the book so valuable to the practitioner, as distinguished from the undergraduate; it is essentially a treatise for post-graduate study, and as such it cannot be too warmly commended.

Ellis's Demonstrations of Anatomy. Being a Guide to the Knowledge of the Human Body by Dissection. Twelfth Edition, Revised and Edited by Christopher Addison, M.D., B.S., F.R.C.S. New York: William Wood and Company, 1906.

But little can be said in added commendation of this book, which has constituted a popular guide for dissecting among medical students both here and in England for many years. In the present edition all the well-known features have been retained, but the advances made by the science of anatomy have necessarily produced appropriate changes. The subject matter has also been rearranged so that it follows the course of dissection now ordinarily practised by students, beginning with the simpler anatomy of the upper and lower limbs and ending with the more complex parts of the head and the body cavities. There are numerous illustrations, many of them in color, and the book is well made. It will no doubt continue to be for many years an efficient aid for the medical student in the dissecting room.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Nineteenth Annual Meeting, Held at Cincinnati, September 20, 21, and 22, 1906.

Dr. John Young Brown of St. Louis, President.

Kidney and Colon Suspension by the Use of the Nephrocolic Ligament and Gerota's Capsule.—Dr. Howard W. Longyear of Detroit described this ligament as formed by an aggregation of fine fasciculi originating in and identical with the fibrous tissue forming the framework of the fatty capsule of the kidney, which, after enveloping the kidney in a fine network, passed downward and were inserted into the posterior wall of the ascending colon on the right side, and the descending colon on the left side. Its structure, as well as its action, might be compared to that of the network covering a balloon, the cords of which descended downward and supported the car. The kidney was the balloon and the cecum the car; the kidney descended or not, according to the laxity of its supports and the degree of traction exerted on it by the cecum. The writer claimed that the traction thus exerted on the kidney by the bowel was the prime factor in the causation of nephroptosis, and as the duodenum was also displaced by reason of its adherence to the fatty capsule, the first object of attainment in any operative procedure should be the suspension of the bowel. To do this he isolated the nephrocolic ligament through the usual incision (though shorter) in the loin and slung up the bowel by overlapping and sewing flaps made from Gerota's capsule through the loop of the ligament. This also held the kidney in suspension, but this object he considered second in importance to the suspension of the bowel.

Fixation of the Kidney by Shortening of the Nephrocolic Ligament.—Dr. Charles A. L. Reed of Cincinnati presented a brief clinical report of cases operated upon by the application of the principle, but a modification of the technique, presented by Dr. Longyear at the meeting last year. The essential modification of the technique consisted of the control of the nephrocolic ligament through an oblique incision in the intercostal interval.

The Technique of Kidney Fixation.—Dr. J. Henry Carstens of Detroit pointed out that to fix a kidney permanently it was necessary to resect the fibrous capsule and fix this firmly to the muscle as near to the normal position as possible. Only in this way could a kidney be firmly and permanently fixed. He described a simple operation which he said could be done in ten minutes through a very small opening, and which would give permanent results, and it seemed to him an ideal method of permanently fixing a kidney.

Dr. Herman E. Hayd of Buffalo said it was not possible to fix a kidney unless one delivered it so as to produce a certain amount of adhesive union between the kidney and the loose structures which it had occupied so long.

Dr. Earl Harlan of Cincinnati called attention to the very wide range of pathological anatomy attendant upon kidney dislocations, and showed that operative procedures must be based upon a correct rearrangement of the normal anatomy of the parts in the right upper quadrant.

Porro Cesarean Section for Pregnancy with Complicating Fibroids.—Dr. James F. Baldwin of Columbus, O., said that, in cases of pregnancy complicated with fibroids, unless the latter were so small as to be negligible, a maternal mortality of over 30 per cent. and a fetal mortality of probably 50 per cent. obtained. Porro cesarean section, with proper surroundings and competent operator, should give a maternal mortality of only about 5 per cent., and practically no fetal mortality whatever. Hence this operation should be uniformly advised in this class of cases.

Uterine Fibroids Complicating Pregnancy.—Dr. Marcus Rosenwasser of Cleveland, O., offered a report of a Porro cesarean section successfully terminated as an additional contribution to papers peviously read before the Association and published in its Transactions of 1896 and 1899. In this case the pelvis was obstructed by an immovable subperitoneal fibroid located in the posterior wall of the lower uterine segment. The operation had been planned for the onset of labor at term, but owing to rupture of membranes and prolapse of cord became an emergency operation at the beginning of the ninth month. Mother and child were saved.

Dr. E. Gustav Zinke of Cincinnati said he had delivered two women in whom tumors were discovered after delivery, not before. The tumors were intramural, very small, one the size of a walnut, the other the size of a hen's egg. In the first case of interstitial fibroids he had seen the woman had been in the hands of a midwife, and when it was found impossible to effect delivery in the usual manner the speaker was called in and did a cesarean section. The fetus had been dead for some time, and the woman died within forty-eight hours of sepsis. When pregnancy was far advanced a fibroid tumor was an extreme source of danger to the woman, especially if it was subperitoneal.

Dr. Oscar H. Elbrecht of St. Louis mentioned a case of fibroid tumor complicating pregnancy at the fourth month. It was subperitoneal and situated in the anterior uterine wall. He removed the tumor and the woman went on to full term.

Dr. Robert T. Morris of New York operated for the removal of a subperitoneal fibroid at the fifth month of pregnancy in a patient who was having a miscarriage. He operated with a desperate chance of trying to save the child. The patient was nearly fifty years of age, this was her only pregnancy, and a great deal depended on the birth of a child in the family. The labor pains ceased after he had removed a fibroid about as large as his fist; she went on to full term and was delivered of a living child.

Dr. Edward J. Ill of Newark, N. J., did not think the impression should go out from the Association that every woman who had fibroids ought to have the uterus removed or a cesarean section done. The indication should be drawn closely. If there was obstruction in labor, then operation was indicated. With all the cases he had seen—he did not recall how many—he had only once done a cesarean section for fibroids.

Dr. Joseph Price of Philadelphia said that these cases, when recognized early, particularly those with pedunculated fibroids, if they fell into the hands of skillful operators, could be operated and the fibroids removed, the patient going on to term and without premature deliveries or abortions. He cited several cases in point.

Dr. Frederick Blume of Pittsburg cited a case in which he did a supravaginal hysterectomy for a fibroid tumor complicating pregnancy.

Dr. Hugo O. Pantzer of Indianapolis cited a number of cases of fibroid tumors complicating pregnancy. He was called to see the first after the expiration of ten days. The woman had given birth to a little child; had developed fever, and at this time was passing a fibroid which had become gangrenous. In the second case he had been called to deliver a woman who had been in labor forty-eight hours. A large tumor was found located at the fundus, and within four days this tumor sloughed away. In the first case the sloughing fibroid was removed with forceps; the patient made a good recovery and has since again become pregnant. In the second case the tumor gave evidence of sloughing on the third day after delivery, and within twenty-four hours he operated per vaginam, removed the fibroid, and the woman made a beautiful recovery.

Dr. J. Henry Carstens of Detroit said that fibroid tumors were quite frequently detected during pregnancy. If one found a small fibroid in the cervix which caused symptoms, it could be removed per vaginam; this would

save the woman a severe labor. If the fibroid was a large one and situated higher up, and there was likelihood of its interference with labor, one could operate and remove the tumor whether the woman was three or six months advanced in pregnancy, and save her future trouble. If the uterus contained multiple fibroids and there was good reason to suspect considerable trouble on account of their interference with pregnancy, he thought it would be well to do either an abdominal or a supravaginal hysterectomy, according to the particular case. If one was required to do a cesarean section, and there was a very large fibroid to deal with, the fibroid should be removed and the uterus saved.

Abdominal Section for Trauma of the Uterus.—Dr. Charles E. Congdon of Buffalo, N. Y., related a case in which there was puncture of the nongravid uterus, with prolapse of the bowel; as a result of violent traction sixteen inches of gut was torn away. Abdominal section, with intestinal anastomosis, was resorted to promptly, and the uterine laceration repaired; this was followed by recovery of the patient.

Dr. Edwin Walker of Evansville, Ind., reported a case of rupture of the uterus with prolapse of the intestine. When called, he found a handful of intestine presenting at the vulva. This he replaced in the vagina, applied a tight binder, removed the woman to a hospital, opened the abdomen, and found that a length of thirty-one inches by actual measurement with mesentery was torn away. He resected the intestine, used a Murphy button, did not employ any sutures in the uterus, as the parts fell together so well, then closed the abdomen, and the patient made a good recovery.

Dr. Rufus B. Hall of Cincinnati believed perforation of the uterus was not infrequent, especially in cases of abortion. He had a curious experience in his service at the Presbyterian Hospital a few years ago. Within eight days he had five patients in the charity ward with perforated uteri who had produced abortions on themselves. These patients were suffering from various stages of infection. All of them were treated, when there was pus present, by vaginal section; three recovered and two died.

Dr. James F. Baldwin of Columbus, Ohio, related a case which he saw in consultation with Dr. Hall many years ago, the patient having punctured the uterus in trying to bring on abortion. There was an enormous amount of pus discharged through the vagina, and the woman promptly recovered. He related other instances of perforation of the uterus.

Dr. Walter B. Dorsett of St. Louis said that if asked to attend a case in which there was perforation of the uterus, produced by an abortionist, he would not hesitate to operate. He recalled one case of rupture of the uterus in labor in which nothing was done. The intestine was pushed back and the woman made a very good recovery.

Dr. John Young Brown of St. Louis said that in spite of the teachings of military surgeons, civil surgeons were beginning to realize the importance of penetrating wounds of the abdomen. It did not matter whether the penetration was caused by the curette or a bullet, or was the result of a stab wound, the consensus of opinion among civil surgeons was that all such wounds should be explored.

The Rectum In Its Relation to Diseases of Women.—Dr. H. O. Pantzer of Indianapolis said that the experienced gynecologist was conscious of an important interrelation existing between the rectum and the female genitalia, both in health and disease. A faulty function of either of the relevant organs might arrest or modify the function of its neighbor. Chronic constipation, at times, affected the quantity, frequency, or course of the menstrual flow. The rectal temperature in pelvic diseases had special significance, but the oral temperature was often misleading. The rectal temperature might be anywhere from one-half to three degrees more than the oral temperature. Textbooks were singularly silent on this differential reading.

The Trend of the Times in Appendicectomy.—Dr. N. Stone Scott of Cleveland, Ohio, dealt with the early history of this operation, after which he expressed himself as being fully convinced that the next step in progressive surgery was the perfecting of the technique, with an eye single to the best interests of the patient, even to the smallest detail. Mere recovery was no longer all-sufficient. The ideal condition was health. Operation approached the ideal in proportion to its elimination of time, pain, and danger in illness. These undesirable elements might be more surely and fully eliminated than we had been accustomed to think possible, if in addition to the essentials heretofore considered necessary due attention was given to certain points which had been too long neglected. The first of these was the choice of anesthetics, but the ideal anesthetic had yet to be discovered. The incision should be large enough to give access to the field of operation. The extent of the skin incision was of no importance, except for cosmetic effect. In aseptic cases the fascial separation should be only sufficient to admit the tip of the index finger. This was crowded through the soft parts, which were easily dilated to admit the entire length of the finger. Given an anesthetic with little, if any, attendant nausea, an incision so short as to close of itself, there was no physiological reason for the recumbent posture. But the ideal operation could be performed only upon an ideal patient; one who was intelligent, obedient, hopeful, and of good recuperative ability, both mental and physical, having well-developed muscle and fascia, without excess of fat, and a movable appendix with a good mesentery; one whose condition was uncomplicated by intercurrent disease or by severe sequalæ, the result of previous attacks.

Points Commonly Contested in the Diagnosis and Treatment of Appendicitis.—Dr. Joseph Price of Philadelphia had found in the reports of some good hospitals that patients suffering from this disease remained in the medical wards until dead, no surgical efforts being made to save them. This simply meant that the pure clinician did not yield the point that it was a surgical affection. It also meant that a clinician had not a precise knowledge of pathology; that he had not served his apprenticeship as a resident or an aid to a surgeon. When the operations for appendicitis were complete, reopenings or secondary operations for a variety of complications were not necessary. One prominent operator reported twenty-four cases of ileus in his work. This simply meant that his work was defective. Waiting and watching should not be taught or practised either in private or public under skilled or unskilled observation. Most good surgeons admitted that they were distressed and unhappy while watching and waiting in an appendicitis that had not been operated upon. A perforation, a spreading infection did thrice more harm, and killed thrice as many patients as an inexperienced operator in an early operation; the patient's chances were lessened by holding off until a well- or illy-defined multiple abscess or abscesses had formed.

The Diagnosis and Surgical Treatment of Injuries to the Diaphragm.—Dr. John Young Brown of St. Louis selected this subject for his presidential address. From a careful analysis of the cases coming under his observation he was convinced that there were present in but few of them symptoms on which a positive diagnosis of injury to the diaphragm could be made, and that in many cases when extensive injuries to the abdominal viscera were present the patients were apparently in excellent condition, and presented practically no symptoms. He believed, therefore, that in all penetrating gunshot or stab wounds of the chest, where from the location of the wound it was reasonable to conclude that injury to the diaphragm was possible, the existence or nonexistence of such injury should be determined by proper exploration. Positive symptoms in these cases were generally the signals of peritonitis, and peritonitis of this character was usually fatal. If this view was correct, how should we explore through the chest or

through the abdomen? A penetrating wound of the diaphragm was a penetrating wound of the abdomen, and an exploration to determine the presence of such an injury which did not enable the operator to repair, if present, the associate injuries to the abdominal viscera should not be undertaken. To sew up an injured diaphragm and leave a perforated bowel or stomach would certainly prove disastrous. Through an abdominal incision the extent of injury to both diaphragm and abdominal viscera could be absolutely determined. If it was found that the wound in the diaphragm was so situated that it could not be repaired through an abdominal incision, thoracotomy could be done at the site of the chest wound, resecting an inch or two inches of rib. With the hand in the abdomen, the diaphragm could be pushed into the thoracotomy wound, making the work of repair quite easy. A method which he had found very useful in dealing with injuries of this character consisted of leaving both ends of the first suture long, using one as a tractor. This method enabled the operator to work through a very small incision, and would frequently do away with the necessity of resecting more than a portion of one rib. The mortality of this work would always be high. Many of these cases were mortally wounded when seen by the surgeon. There were, however, quite a few whose injuries could be repaired with satisfactory results if operation was undertaken early. He urged that more attention be paid to penetrating wounds of the lower chest, and that early exploration be undertaken as a routine procedure in all cases where injury to the diaphragm was suspected.

Reflex Dyspepsias in Abdominal and Pelvic Disease, and Their Surgical Treatment.—Dr. Herman E. Hayd of Buffalo, N. Y., said (1) the intimate nervous supply of the abdominal and pelvic organs often made one organ reflect and simulate symptoms which represented the disease of the other. Chronic appendicitis, retroversions, and floating kidney very frequently produced very marked dyspeptic symptoms. Gall-bladder disease and often stones without jaundice were treated for simple dyspepsia. (2) He made a plea for the more careful examination of operative cases. Frequently many organs were involved in the symptomatology, and the patient remained uncured because of incomplete surgery. (3) Serious stomach diseases producing various dyspeptic symptoms, such as ulcer, hourglass contraction, pyloric obstruction, chronic gastritis with dilatation and early cancer, should be placed among the curable surgical diseases and should receive the unquestioned benefits of early surgical interference.

Intestinal Obstruction Due to Gallstones.—Dr. Miles F. Porter of Fort Wayne, Ind., said that gallstones might obstruct the bowel in five different ways, obturation being the most usual form. The stone might get into the bowel through the common duct, but usually entered from the gall-bladder by obturation, via the duodenum, and might lodge anywhere from the pylorus to the anus, but in the majority of cases was found in the ileum. As a rule the gut was not damaged, but gangrene and perforation occurred if the obstruction was not promptly relieved. The symptoms were those of acute, but often not complete, obstruction of the bowel. A previous history of gallstone disease was found in most cases. The presence of a migrating tumor originating in the gall-bladder, or a stationary tumor of egg size and shape, and hard, was of great diagnostic value, but it was absent in most cases. Tenderness and rigidity were not present until late. Shock was not marked. Multiple attacks of bowel obstruction were significant of gallstone ileus. Exploratory incision was the best means of making the diagnosis in the majority of cases. The mortality was 50 per cent. This large mortality was due in no small measure to the advice given by many authors to delay operation until a fair trial of medical treatment, massage, etc., had failed.

Some Points in the Diagnosis and Treatment of Accidental Hemorrhage.—Dr. Adam H. Wright of Toronto said that several differences of opinion were prevalent as to both the diagnosis and treatment. The following procedures were conspicuous in this regard: Rupture of the membranes, plugging the vagina, accouchement forcé, and cesarean section. The mortality rate of accouchement forcé, when the patient was suffering from shock, and the uterus was tetanically contracted, was, in his opinion, 100 per cent. He knew of no operation in obstetrics or surgery respecting which one could speak more definitely. He had had no experience with vaginal or abdominal cesarean section for accidental hemorrhage. In the case of either concealed or combined internal and external accidental hemorrhage, with the patient suffering from shock and a cervix as hard as iron, any operation would probably be unjustifiable. It might happen, however, that internal hemorrhage was taking place into a uterus whose walls were stretching rapidly, and the loss of blood was the chief factor. If, in such an emergency, it was not possible to dilate the os and deliver soon enough to save life, some form of cesarean section might be advisable.

Diffuse Peritonitis.—Dr. John B. Murphy of Chicago reported thirty-six consecutive cases of general suppurative peritonitis from perforation, with one death. In treating this condition he emphasized the importance of relieving pressure and of instituting drainage, doing as little surgery as possible. The patient should be put in a sitting position both before and after operation, so as to keep the infective material out of the diaphragmatic zone. At the time of operation usually the patient had all the infection he could possibly carry; he or she, as the case might be, was handicapped, and it was the duty of the surgeon to eliminate that infection or intoxication as much as possible, and in doing so care should be taken not to abrade another square inch or half of a square inch of surface so as to admit more infective material. The patient should be tided over for a few hours and his local resistance built up by washing out the blood with normal salt solution. Antistreptococcic serum should be employed. Little or no food should be given, as what hastened absorption of infective material in the diaphragmatic zone was peristaltic action.

Abuse of Purgatives.—Dr. Edwin Walker of Evansville, Ind., said that purgatives were probably the most widely used remedial agents. They were used by the public and profession under widely adverse conditions. This promiscuous use was productive of much harm. Our knowledge of the physiology of the intestinal canal was painfully deficient and its pathology was not well understood. The best authors differed as to the physiological action of purgatives. There was certainly a close resemblance between infections of the intestinal canal and the action of purgatives. All of these considerations suggested care in the use of cathartics. In constipation purgatives were contraindicated; in diarrhea they were limited in value. Biliousness was too vague a term to be considered as an indication for their use. They should rarely be used in the preparation for surgcial operation, or the complications following. Increased knowledge would no doubt materially curtail their use.

A Consideration of the Factors Which Have Lowered the Operative Mortality and Have Improved the Postoperative Results.—Dr. X. O. Werder of Pittsburg, Pa., said, in summing up, the causes to which he attributed his better results, both in regard to operative mortality as well as postoperative morbidity, were: (1) A more simple and better aseptic technique, including the wearing of rubber gloves for all hands concerned in the operation. (2) Better diagnosis and more careful preparation of the patient, especially the acute inflammatory cases, whose abdominal section is delayed at least three weeks after the subsidence of all acute symptoms. (3) The employment of a trained, absolutely reliable first assistant. (4) Centralization of all operative work, enabling the operator to give the greatest

amount of personal attention to his patients. (5) The careful closure and covering of all raw surfaces in the peritoneal cavity. (6) The exclusive use of catgut prepared under personal supervision. (7) A trained anesthetist who administers a minimum amount of anesthetic consistent with good work.

The Management of Bowel of Doubtful Vitality in Operations for the Relief of Strangulated Hernia and Intestinal Obstruction.—Dr. Rufus B. Hall of Cincinnati said that the injured bowel in all these cases could be divided into three groups as soon as the operation had progressed to the stage where it could be inspected. (1) Those cases in which it was clearly evident that we did not have to make a resection; (2) those in which it was positively certain that a resection must be made; (3) those in which the surgeon was always in doubt as to the vitality of the injured portion of bowel. Whether it occurred in internal obstruction or in incarcerated bowel in a strangulated hernia, it was to the treatment of this uncertain condition that he desired to call attention. He had devised a means which had proved eminently satisfactory to him in a number of cases. The method consisted in employing a single layer of iodoform gauze about three inches broad, placing it against one side of the mesentery and carrying it over the diseased bowel until it rested upon the mesentery upon the opposite side, extending a couple of inches beyond the bowel of doubtful vitality upon each side; this loop of bowel surrounded by the gauze was placed just inside the abdomen. The wound was dressed by leaving one or two stitches untied; or if the operation had been for hernia, as an open wound, leaving the end of the gauze surrounding the bowel projecting out of the wound a foot or more, so there was no danger of losing it inside. The method was not applicable in all kinds of bowel injury, and was not advised except in certain definite conditions and surroundings. Cases were reported illustrative of the method.

The Utilization of the Broad and Round Uterine Ligaments in Supravaginal Hysterectomy.—Dr. Walter B. Dorsett of St. Louis pointed out that in impacted cases of myomatous uteri, as well as in large abdominal tumors of the uterus, a tendency to a shortening of the vagina followed the operation, and a sacculation of the bladder also was apt to ensue. This was obviated by folding the remaining portions of the broad and round ligament on themselves and attaching them to the stump of the uterus.

Some Observations and Experiences Respecting the Symptoms and Treatment of Atresia Vaginæ.—Dr. Augustus P. Clarke of Cambridge, Mass., said that inflammation occurring in the vaginal tract might become the exciting cause of atresia vaginæ. Adhesions of the labia or other parts in the vicinity might interfere with the normal parturition, if not prevent the menstrual flow. In atresia hymenalis the obstruction would usually be complete, and this gave rise to collections of blood or mucus high up in the vaginal introitus. Such a condition could be relieved only by surgical measures. The author had met with cases of atresia in which firm bands of cicatricial tissue had formed laterally between the middle and upper segments of the vaginal walls. Traumatic cases could often be cured by resort to operative measures. Congenital cases could not always be satisfactorily relieved. In those cases in which the uterus and Fallopian tubes were in a mere rudimentary condition, surgical attempts for relief would for the most part prove useless. In two cases in which the cause was due to extensive laceration and sloughing of the parts, on account of traumatic lesions during parturition, subsequent pregnancy failed to take place. In the treatment of cases in which surgical measures had been resorted to the employment of hard vaginal dilators and iodoform gauze was found to be of much benefit. In nearly all cases of the accidental or acquired atresia relief might be secured by operative treatment. In congenital cases radical means for relief would prove useless.

Preservation of the Vault of the Vagina in Pelvic Operations.—Dr. A. Vander Veer of Albany, N. Y., said that one could divide the life of a female into three periods —puberty, marriage and the birth of the first child, and the menopause. At the period of puberty we had to consider carefully the functions of the ovaries and malpositions of the uterus more particularly. At the time of her first confinement we had to consider the possible lesions that might present, notwithstanding the most earnest care on the part of the obstetrician. We should consider carefully the possible morbific changes that came at the time of the menopause. The paper dealt more especially with lesions produced when, in an operation, the vault of the vagina was encroached upon. In malignant growths the surgeon was in doubt in this region of the body as to how much normal tissue should be preserved. He was led to emphasize the axiom of practice to preserve normal tissues as much as possible, and under no circumstances to remove healthy organs. Vaginal hysterectomy for varied lesions of the uterus required separate consideration in each individual case, with due regard to postoperative contractures and disturbance of function of other nearby organs. This was seen at times in a constant dragging pain, due to disturbance of the sigmoid flexure and interference with the rich blood and nerve supply of the pelvic organs. Most commonly it was expressed in bladder or rectal conditions. In abdominal operations there was a difference in the nature of the procedure as between a malignant or non-malignant condition. Whatever method was adopted, he believed the one important object in view should be to bring the stump well up in position that it might hold the vault and fornix of the vagina, prevent sagging, and especially the dragging upon any of the nerve trunks or large vessels. The old extraperitoneal method of hysterectomy preserved the vault of the vagina very acceptably.

Peritoneal Adhesions.—Dr. Robert T. Morris of New York said that favorite fields for chronic peritoneal adhesions were the region of the cecum and appendix, the gall-bladder, the sigmoid region, and the pelvis. He thought the greatest amount of disturbance calling for attention on the part of the surgeon was caused by adhesions in the region of the gall-bladder, for in this region we were near the great semilunar ganglion, and the organs in the vicinity of these adhesions were more movable than those in the vicinity of the other common groups of lesions. Next in the order of importance he believed to be the group of adhesions in the region of the cecum and appendix. Adhesions in the pelvic region, although extremely common, did not call for so much interference on the part of the surgeon as the other groups of adhesions, for the reason that the viscera involved rested upon the pelvic floor and were not subject to such constant and varying degrees of friction. Adhesions about the sigmoid gave rise to comparatively little disturbance. As to the method of caring for adhesions, he first began by simply separating them. While in Berlin he saw Martin rubbing adhesions with oil. He tried that for a while, without getting marked results; then he followed the plan of filling the peritoneal cavity with saline solution after operation. But this was not wholly satisfactory, because the salt solution was absorbed too rapidly. He then adopted the method of using the aristol film, because he noticed when raw peritoneal surfaces were exposed to the air there was a tendency for a lymph coagulum to form. If one included in the lymph coagulum an insoluble material like aristol, he included something which offered a mechanical obstacle to readhesion at that point. He had found practically that the Cargile membrane would prevent the recurrence of adhesions very regularly, although not always completely. Sometimes the surgeon might have to repeat the operation. He was unwilling to state which was the better of the two, the Cargile membrane or the aristol film. In their proper places both were distinctly valuable.

Officers.—The following officers were elected for the

ensuing year: *President*, Dr. Robert T. Morris of New York; *First Vice-President*, Dr. George W. Crile of Cleveland, Ohio; *Second Vice-President*, Dr. Charles L. Bonifield of Cincinnati; *Secretary*, Dr. Wm. Warren Potter of Buffalo, N. Y., reelected; *Treasurer*, Dr. X. O. Werder of Pittsburg, Pa.; reelected. The determination of the time and place of the next meeting was left to the Executive Council.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirtieth Annual Meeting, Held in Cleveland, O., May 31, June 1 and 2, 1906.

THE PRESIDENT, DR. MILTON B. HARTZELL OF PHILADELPHIA, PA., IN THE CHAIR.

Address by the President.—Dr. HARTZELL, in his opening address, said the profession at large was rather inclined to regard dermatology as a specialty which dealt, for the most part, with trivial affections, and the dermatologist himself was, in some degree at least, responsible for this view, for certain fields of research had been almost, if not entirely, neglected by him. No other tissue of the body offered such extraordinary opportunities for the study of morbid processes in general as the skin. It was always possible to obtain what was practically living material for microscopic study, and to observe the progress of disease from day to day; yet the general pathologist, if we might judge from the text-books on pathology, had given almost no attention to the skin, while the dermatologist, until a recent period, had made but little more use of his opportunities. Among the fields of research in which Dr. Hartzell urged the dermatologist to become more active were the causation of cancer; the effects of traumatism; the changes that occurred in epithelium; the problems connected with the subject of immunity; the antagonism occasionally observed between general diseases and diseases of the skin; the physiological action of drugs on the skin; the pathology and histopathology of drug eruptions; experimental therapeutics, especially in connection with the various infections; the rôle played by toxins, and lastly, the eruptive fevers, which he believed properly belonged to this specialty more than to any other department of medicine.

Dermatitis Exfoliativa.—Dr. BURNSIDE FOSTER of St. Paul, Minn., who read this paper, stated that during the past fifteen years there had fallen under his observation quite a number of cases which he had grouped together under the general class of exfoliative dermatitis, because that name was descriptive of all of them, and because the dermatologists were by no means agreed as to the exact nature of the different types of cases which in a general way were to be described by the above name. Among the cases of this general type that he had seen, and which he reported in detail, were four cases of dermatitis exfoliativa neonatorum; also two or three cases which he believed were instances of the condition first described by Hebra as pityriasis rubra, and five cases of acute, idiopathic exfoliative dermatitis. The most interesting problem connected with this group of cases, Dr. Foster said, was whether we had to do with one disease, varying in severity and extent in different cases, or whether we had several distinct diseases to deal with. Until more was known regarding them, he was in favor of retaining only the term dermatitis exfoliativa, adding the word epidemica or contagiosa for those cases where the infectious nature of the disease was apparent.

Dr. WILLIAM A. PUSEY of Chicago thought we could not hope to arrive at any definite grouping of these multiform dermatoses, which presented only one feature in common, namely, dermatitis.

Dr. A. RAVOGLI of Cincinnati said the character of the exfoliation or desquamation was an important factor in distinguishing between the various types of exfoliative dermatitis. He agreed that pityriasis rubra pilaris was a definite type, and identical with the lichen ruber acuminatus of Hebra.

Dr. JAY F. SCHAMBERG of Philadelphia said that in the exfoliative types of dermatitis we were dealing with certain objective clinical phenomena which might be produced by a multitude of causes, both external and internal. We designated the condition dermatitis exfoliativa if a generalized redness of the body, followed by exfoliation of the epithelium, existed. There were various types of this disease, including the acute type, which ran its course in from four to six weeks.

Dr. JOSEPH GRINDON of St. Louis said it seemed to him that to call all forms of exfoliative dermatitis by one name would not be a step in the direction of simplicity, but, on the contrary, would merely complicate the subject. It was just as necessary to take the course of the disease into consideration as the subjective symptoms.

Remarks on Syphilitic Alopecia.—Dr. HERMANN G. KLOTZ of New York read a paper on this subject, in which he offered the following conclusions: (1) Alopecia, or loss of hair, was *not* a common or regular symptom of the early stages of syphilis. (2) The slight loss of hair which was commonly taking place in healthy individuals as the result of the physiological change of the hair continued its existence through and beyond the course of syphilis, and must be taken into consideration before attributing to syphilis a loss of hair so slight as to pass unnoticed, or scarcely attract the patient's attention. (3) The same rule applied to numerous cases of slight seborrhea of the scalp, which under ordinary conditions would not be considered worthy of notice or treatment. (4) In a certain number of cases, syphilis might be accompanied by a diffuse loss of hair which might extend more or less over the entire scalp, varying in degree, similar to that observed after other infectious diseases, such a typhoid fever, erysipelas, etc. (5) In the absence of any discoverable local changes in the skin, this alopecia was apparently the result of malnutrition of the hair, its appendages, and the entire skin, as part of a general modification of the entire organism by the infection with the virus. (6) Such an alopecia was therefore not strictly a symptom of syphilis, directly due to the virus, but rather a complication. (7) Such an alopecia was directly dependent upon and in most instances proportionate to the general symptoms which might accompany the second period of incubation, and usually made its appearance several weeks after the onset of these prodromal symptoms, similarly to other infectious diseases, like typhoid fever. (8) Although such an alopecia might be very extensive, and affect other portions of the body, it showed a tendency to more or less complete restitution of the hair, unless the patient was too advanced in years, or was a subject of hereditary tendency to baldness. (9) An alopecia occasionally occurred in the form of ill-defined, irregular, small, sometimes coalescent patches of baldness, distributed principally over the back and upper portions of the scalp, and giving it a mangy or moth-eaten appearance. (10) Such an alopecia was observed almost exclusively in syphilitics, and was so characteristic that with extremely rare exceptions it was diagnostic of syphilis of the affected individual, either acquired or hereditary. (11) Such an alopecia was a characteristic symptom of syphilis, and almost always occurred at a period more or less remote from the time of infection, usually not before the end of the first year. It generally followed a very tedious course, although terminating in restoration of the hair. (12) In the absence of any discoverable anatomical changes of the skin, due to a local specific process, it was very difficult to explain the origin of this alopecia in patches.

Dr. GEORGE T. JACKSON of New York agreed with Dr. Klotz that alopecia was not as common a feature of syphilis as was ascribed to it by the text-books. The only type of

syphilitic alopecia that he regarded as absolutely pathognomonic was that in which the hair had a ragged, mangy appearance, as though it had been hacked off, or clipped with a pair of dull scissors. In this type, the patches were very irregular. It was observed, in his experience, more frequently before the end of the first year than afterward.

Dr. Robert W. Taylor of New York classified the various types of syphilitic alopecia as follows: (1) Alopeciaphobia, by which he meant an ordinary defluvium capillorum, the danger of which was much magnified in the mind of the patient, who was afraid of losing his entire hair. (2) A shedding of the hair, such as occurred in many adynamic diseases. (3) The moth-eaten, characteristic form of syphilitic alopecia, occurring in spots. (4) An alopecia due to syphilitic lesions.

Dr. James Nevins Hyde of Chicago said that while the moth-eaten appearance of the hair to which Dr. Klotz had referred was very characteristic of syphilis, and was usually accompanied by other well-marked manifestations of that disease, he had seen distinct exceptions to the rule. He reported a case in which this typical form of syphilitic alopecia was observed in a patient who at the time had few if any other symptoms of a generalized syphilis.

Dr. Charles J. White of Boston said he had seen two cases of this moth-eaten type of syphilitic alopecia, which went on to total and permanent baldness.

Dr. Joseph Grindon of St. Louis had seen marked alopecia of this type occurring in individuals who gave a very uncertain syphilitic history. Personally, he regarded the condition as absolutely pathognomonic of syphilis, but he did not believe it occurred in hereditary syphilis.

Dr. Stelwagon said he could hardly agree that there was any type of alopecia that was invariably syphilitic.

Dr. Robert W. Taylor of New York thought the moth-eaten patches of alopecia on the back of the head were as pathognomonic of syphilitic infection as was the serpiginous syphilide, which Ricord used to refer to as the *signature de la syphilis.*

Syringocystoma.—Dr. Charles J. White of Boston, Mass., reported this case, and discussed the nature of the lesions. The patient was a young girl with numerous small *café au lait* tumors on the neck. Pathologically, these flat nodules were epithelial branches and dilated cysts lying in the middle strata of the corium, and most probably represented new growths and cystic dilatations of the sweat ducts.

Dr. Hartzell showed some photomicrographs of his own case, which he reported about two years ago, in which it was quite easy to demonstrate that the newly-formed epithelium took its origin from the hair follicles. Furthermore, it was also quite apparent that the cysts had their origin in the hair follicles.

The Report of a Case of Parakeratosis Variagata.—Dr. Henry G. Anthony of Chicago reported this case in detail, and said it was not established that dermatitis psoriasiformis nodularis, parakeratosis variagata and *erythrodermie pityriasique en plaques disseminées* were different manifestations of one and the same disease, as some writers believed, and until their identity was definitely determined he considered it advisable to regard these eruptions as separate and distinct disorders. The points which they presented in common were their superficial character; the fact that they appeared rather suddenly in young, healthy individuals; that there were no succeeding groups of the eruption, but a steady imperceptible increase of lesions; that there was no itching, and that the disease was unaffected by treatment. The case presented by Dr. Anthony was that of a man, 23 years old, a laborer by occupation. The essential feature of the eruption was a combination of very slight, superficial erythema with a varying degree of pigmentation, presenting the appearance of disappearing plaques of lichen planus, and forming three kinds of lesions. 1. Light brown colored plaques in which there was erythema, but with little pigmentation. 2. Chestnut brown colored plaques in which there was erythema with a good deal of pigmentation. 3. Bluish colored placques which were exclusively caused by pigmentation.

Dr. S. Pollitzer of New York said the original description of parakeratosis variagata was as different from the case shown by Dr. Anthony as it was possible for two skin diseases to be. In the original case there was apparently a reticulation of almost the entire cutaneous surface, showing normal skin between slightly raised, glistening linear areas, strongly suggesting an extensive reticulated lichen planus annularis. In fact, Besnier, who saw the case before Unna, looked upon it as probably some form of lichen planus.

Dr. James C. White of Boston said that in his case, even in the most advanced lesions, the pigmentation or coloration did not advance beyond a very slight degree, and was what might be called rust red.

Dr. Anthony, in closing, said that since the original description of parakeratosis variagata, to which Dr. Pollitzer had referred, was published in 1890, a number of cases had been reported in which the reticular arrangement of the lesions was entirely absent. He was inclined to believe that Dr. Pollitzer laid too much stress upon that single feature of the eruption, which personally he regarded as of very little importance.

Elephantiasis of the Penis and Scrotum as a Result of Syphilis.—Dr. A. Ravogli of Cincinnati, O., reported this case, which confirmed the views of Hill that elephantiasis in this country was not of very rare occurrence, and was more frequently found among the colored race. It was only sporadic, with no relation to filariasis, and in the few cases which had been under his observation, syphilis was at the bottom of the affection. He called attention to the fact that even in countries where elephantiasis was endemic, other etiological factors than filariasis, such as trauma, and above all, syphilis, were important causative elements.

Dr. Robert W. Taylor said that cases like those described by Dr. Ravogli were usually met with in old syphilitics in whom the condition was complicated by trauma, or by a gonorrheal or staphylococcic infection.

Dr. Martin F. Engman of St. Louis said the specific cell of syphilis was certainly a plasma cell. That fact had been demonstrated by Unna and others in their investigations of tuberculosis and syphilis. The speaker said that in his experience it was unique to see a leucocytosis in syphilis, and when it did occur he regarded it as secondary and of staphylococcic or other origin.

The Development of Successive Initial Syphilitic Lesions, and the Pathology of Syphilitic Infection.—Dr. Robert W. Taylor of New York read this paper and reported a number of cases coming under his observation in which there were a number of successive initial syphilitic lesions. For many years, he said, the solitary character of the syphilitic lesion was claimed, and was generally accepted. In the course of time, however, this dictum was disputed, and it was conceded that the evolution of syphilis in some cases began by the appearance of several lesions, but even then the number was restricted to two or three. With advancing study and observation our ideas of the multiplicity of the syphilitic chancre had greatly expanded, so that we now recognized the fact that it was not uncommon to see from three or four to thirteen or fifteen lesions. It had further been shown by reliable statistical reports that in about 25 per cent. of all cases of syphilitic infection the initial lesion was multiple. Some authors admitted that successive chancres might occur as late as the twentieth day after infection, while a minority claimed that such reinfection was impossible, since at that time the entire organism had been infected, and thus been rendered immune. In clinical practice the occurrence of successive chancres might be due to simultaneous or later infections from a single source, and these might be called

cases of autoinfection. In some cases there was a strong probability that the successive chancres were due to identical secretions derived from another syphilitic individual, so that the victim was poisoned from two sources. These cases, therefore, might be termed instances of heteroinfection.

Dr. William T. Corlett of Cleveland said it was not unusual in his experience to see two, sometimes three, typical indurated lesions in a case of syphilis. In reference to the other type of cases to which Dr. Taylor had referred, where successive lesions developed in the course of syphilis, Dr. Corlett said he had never regarded them in the light of multiple chancres, but rather as lesions resulting from pus infection.

Dr. William F. Breakey of Ann Arbor said that his more recent studies in regard to the development of syphilis had only confirmed his earlier observations, made many years ago, that the excision or cauterization of the initial lesion tended to obscure the diagnosis and had only an unfavorable influence upon the later manifestations of the disease. Of the cases of tertiary syphilis that came under his observation, he could safely say that in nine out of ten the initial lesion had been cauterized, and a false sense of security had thereby been imparted to the patient.

"White Spot Disease" (Morphœa Guttata) and Lichen Planus et Atrophicus.—Drs. Frank Hugh Montgomery and Oliver S. Ormsby of Chicago, Ill., read this paper, which contained the further report of a case which was shown before this Association in Chicago in 1901 and in whom some of the white spots eventually became typical morphea lesions. A similar case was also reported in which the white spots on the upper part of the body were accompanied by areas of scleroderma on the leg. Also a case of lichen planus sclerosus et atrophicus, which was included because of its striking resemblance to the white spot disorder, and also to morphea, and because by many this form of lichen planus was not yet recognized as a distinct clinical type. The object of the paper was to present a clinical and histological study of these cases, together with data from the literature, in the hope of contributing to the solution of the question whether the above named conditions should be recognized as clinical entities or should be considered unusual types of morphea or local scleroderma.

Lymphangioma Circumscriptum.—Dr. S. Pollitzer, in this paper, reported in detail two such cases that came under his observation, and gave a histological and clinical description of the appearance of the growths. He stated that tumors of the lymphatics belonged to the rare pathological manifestations, those appertaining to the superficial layers of the skin constituting clinically one of the rarest of all skin diseases.

Dr. James C. White of Boston said we could scarcely accept the statement of the French writers as to the infrequent occurrence of this disease, as they were too prone to limit their references to their own literature. The speaker said he had reported two cases of lymphangioma circumscriptum, with accompanying dermatitis. In a case of this affection recently seen in Boston, the lesion was situated on the toe, surrounding the margin of the nail. He had never before seen that location involved.

Dr. Thomas C. Gilcrist of Baltimore said that about nine or ten years ago he reported a case of lymphangioma circumscriptum occurring in a girl of twelve. The lesion was about four and a half by eight inches in diameter and occupied the outer surface of the thigh. The history of that case was published in the Johns Hopkins Bulletin.

An Analysis of Sixty-seven Cases of Bullous Diseases of the Skin.—Dr. William T. Corlett of Cleveland, O., after referring to the difficulty of classifying bullous dermatoses, briefly analyzed 65 cases that had come under his observation. These included twenty cases of pemphigus, seven cases of pemphigus foliaceus, two cases of so-called pemphigus of the new-born, fifteen cases of impetigo bullosa, two cases of dermatitis bullosa, twelve cases of dermatitis herpetiformis, three cases of epidermolysis bullosa hereditaria, one case of urticaria bullosa, and five cases of pompholyx. Dr. Corlett said that while he believed that clinical groups of this class of affections were sufficiently distinctive for ordinary diagnostic purposes, yet hard and fast lines could not at this time be drawn between them. There were in each group many cases which conformed to the type, but at the same time a larger number presented departures from the standard which rendered it in many instances a matter of personal opinion as to what group they belonged.

Dr. Burnside Foster of St. Paul said he had seen an epidemic of pemphigus neonatorum of a mild type. All the cases recovered and he had then put them down as case of impetigo contagiosa of the bullous form. Four of these cases occurred in the practice of one midwife and one in the family of a neighbor who had assisted the midwife.

Diet as an Etiological Factor in Diseases of the Skin.—Dr. Henry W. Stelwagon of Philadelphia, Pa., in discussing this phase of the subject, said we knew that certain foods were toxic in some individuals, these constituting the so-called idiosyncrasies. In others, the eruptive phenomena, while not to be attributed directly to the food itself, resulted from overeating, thus giving rise to indigestion, crowding the eliminative organs, and resulting in faulty metabolism. In others, but more especially in those having a cutaneous disease tendency, underfeeding, as well as improper feeding, and overfeeding, might be the deciding factor that called forth the eruption. Further, in many cases, the evil effects were not due to the foods themselves (if in good and fresh condition), but to the toxic and putrefactive changes which they had undergone before or immediately after their consumption. Finally, the possibility of chemical preservatives and not the food itself being the etiological element in some of these cases should not be wholly disregarded.

Diet as a Therapeutic Measure.—Dr. George H. Fox of New York discussed the subject from this standpoint. In the first place, he laid great stress upon the importance of careful regulation of the diet in the treatment of all inflammatory affections of the skin, which included all those skin diseases in which the congestive element was present to a greater or less degree. While diet could not be expected to cure lupus, syphilis, or malignant disease, it certainly improved the condition of the patient and modified the local conditions to a slight extent, and hence might prove of service in nearly all classes of skin diseases. While every physician professed to believe in the efficacy of diet in the treatment of disease, very few were inclined to practice what they preached. The speaker also emphasized the fact that the majority of our patients, and those who were likely to become our patients, were in the habit of eating too much. While it was true that some suffered from malnutrition and needed to be better nourished before their skin disease could be radically cured, it was also true that even these patients could be benefited by a temporary restriction of diet. For every patient suffering from an inflammatory skin disease who was eating too little and suffering from lack of nourishment, there were a score or more who were eating far more than they actually needed and thus feeding the eruption. Dr. Fox expressed his firm belief that an excess of nitrogenous food was prejudicial to the health of both mind and body. It was without doubt the cause of many of the ills which were formerly ascribed to malaria and now commonly attributed to uric acid excess. He always claimed that a change of diet was of great advantage, even if it was from a theoretically good diet to a commonly considered bad diet. A change must be made in the patient's manner of living in many cases of skin disease; otherwise, the wisdom of the physician, with the assistance of the apothecary, would prove of

little avail. The character of the food in the treatment of cutaneous and other diseases was of less importance, perhaps, than the manner in which the food was taken. It was not what the patient ate so much as it was how and when and under what circumstances he ate that tended to the production of an inflammatory condition of the skin. Hasty eating, irregular eating, and meals taken under the stress of excitement and worry were the daily experiences of many of our patients, both rich and poor. In connection with this subject of diet, Dr. Fox said he could not refrain from referring to those two therapeutic handmaidens, exercise and cold baths. Diet, exercise, and bathing constituted the tripod of every trainer, restoring health, imparting strength, and inspiring energy.

Dr. Wm. A. Pusey of Chicago referred to the tendency to cut down the diet of growing girls with the idea that they were eating too much, while as a matter of fact, they were underfed.

Dr. Corlett said that the directions usually given in regard to diet were too general and failed to apply to the individual case. In order to ascertain the dietetic errors or deficiencies one must be specially equipped for making as analysis of the stomach contents. What was one man's meat was another man's poison, and no rule could be laid down to apply to all cases.

Dr. Burnside Foster said he had always thought that the arrangement of the diet of his patients was a most important part of the treatment, particularly in the inflammatory type of skin diseases, and in that connection the personal equation should never be lost sight of. The speaker said he was inclined to agree with Dr. Fox that it was a good idea to learn what your patient was in the habit of eating, and then make just as radical a change as possible. Diet was a good deal like climate: people wanted something different from what they had been accustomed to.

Dr. James M. Winfield of Brooklyn said that fish out of season was probably one of the most injurious articles of diet. Of course, this did not apply to perfectly fresh fish, or to fish in season, but to stored fish, which was very apt to produce urticaria, especially in susceptible patients.

Dr. Frank H. Montgomery of Chicago said there was a certain type of nervous women and girls, and also some men, who were in the habit of eating when they were tired out, or hurried or worried, and he could recall cases where he had been able to control mild attacks of rosacea in this class of patients by instructing them to take a short rest before meals and then eat quietly and masticate their food thoroughly.

Dr. Hermann G. Klotz of New York said that, so far as he knew, psoriasis was common in all countries, civilized and uncivilized; the same was true of eczema, in spite of the various forms of dietary indulged in. Both diseases apparently affected people who lived in entirely different ways and under different conditions.

Dr. Fox, in closing, said he had always maintained that water was the best and cheapest remedy in the pharmacopœia, and when taken freely between meals and in moderation with meals, it would take the place of laxatives and increase the elimination of toxic substances.

Multiple Cancer of the Skin and Keratosis Following the Long-Continued Use of Arsenic: Multiple Ulcerations of the Skin After the Protracted Use of the Same Drug.—Dr. Jay F. Schamberg of Philadelphia, Pa., read this paper, in which he reported in detail the history of a case of multiple epitheliomata in a man who had taken Fowler's solution at intervals during a period of twenty-five years. Among other lesions, he presented a large nodular cancer on the leg, which was not hyperkeratotic. Dr. Schamberg also reported a case of multiple persistent ulcerations of the leg in a woman who had taken arsenic continuously for four and a half years.

Dr. Henry W. Stelwagon of Philadelphia said there had always been a question in his mind as to how far arsenic was directly responsible for these cancerous conditions of the skin. A great many of the skin cancers began as a hyperkeratosis, and the arsenic sometimes produced this. Similarly, in cancers which followed the use of the *x*-ray, the first condition noticed was a hyperkeratosis; the speaker said he had always doubted whether the *x*-ray itself produced the cancer, or simply the hyperkeratosis which eventuated in cancer. The same was not improbable as to arsenic.

Dr. Thomas C. Gilcrist of Baltimore said he agreed with Dr. Stelwagon that the arsenic produced a hyperkeratosis and that the cancer was a subsequent development.

A Contribution to the Histopathology of Some Drug Eruptions.—By Drs. M. F. Engman and W. H. Mook of St. Louis, Mo. The observations contained in this paper were based upon a study of the iodine and bromine eruptions, and the following conclusions were offered: 1. The local eruptive phenomena were prone to occur at points of previous inflammation; about comedoes, acne lesions, seborrhoic lesions, scars, traumata, scratches, etc. 2. Traumata, pressure, or rapid temperature changes might precipitate an eruption in tissues charged with the drug. 3. Idiosyncrasy or susceptibility were factors here, as in other toxic conditions. 4. The glands or follicles of the skin took no active part in the production of the lesions, and when they were involved it was secondary and passive to inflammatory changes about the vessels and in the connective tissue. 5. The gross histological changes in the skin consisted in different degrees of inflammation, from slight changes about the vessels to destructive abscess formation and progressive death of tissue. In their further conclusions, Drs. Engman and Mook described the minute histological changes that led to the formation of these lesions, and stated that this theory might be termed the "rational theory," as it explained all the symptoms of ioderma and bromoderma in a purely rational, chemical, and mechanical manner, and did not depend in its elucidation upon the mysterious and purely theoretical action of the vasomotor system.

Dr. Jay F. Shamberg of Philadelphia said the theory advanced by Dr. Engman was not only plausible but was confirmed by clinical facts in connection with certain diseases. For example, in smallpox an increase in the vascularity of any area of the skin would almost invariably determine the presence of an increased number of lesions in that area. A mustard-plaster applied to relieve the backache of smallpox would usually mark the site of a subsequent confluent eruption. In scarlet fever, the speaker said, the converse of this rule was true, as the areas where continuous pressure had been exerted, such as the garter regions, were usually free of the eruption.

Vegetating Dermatitis, with a Report of Two Cases.—Dr. William Allen Pusey of Chicago, reported these two cases in detail, with histological findings, and compared them with similar cases reported under various names by Hartzell, Hallopeau, Wickham, Wende and Degroat, and Perrin. He expressed the view that we had in these various cases of dermatitis, with vegetations, essentially one process, and that a secondary one. The vegetations were not primary lesions, but were the result of secondary infection, with the consequent production of exuberant growth of both the connective tissue and the overlying epithelium.

Report of a Case of Pemphigus Vegetans (Neumann).—By Dr. J. M. Winfield of Brooklyn, N. Y. The patient was a Polish girl who was kept under observation at the Kings County Hospital from October 30, 1905, to May 5, 1906, when she died. From a study of the literature of the disease, together with the above case, Dr. Winfield deduced the following conclusions: 1. That some of the reported cases were not true examples of pemphigus vegetans. 2. That pemphigus vegetans was a distinct disease, and not related etiologically to the disease commonly

known as pemphigus. 3. That pemphigus vegetans was an infectious disease, running a definite course. 4. That the producing organism was not yet determined. 5. That this organism gained entrance into the body through the mucous orifices and abrasions of the skin. 6. That pathological changes in the kidneys, as evidenced by uranalysis and pathological findings, were not etiologically significant but secondary.

Dr. M. B. Hartzell of Philadelphia referred to the marked disproportion between the amount of the eruption and the constitutional symptoms in some of these cases. He had in mind the case of a Polish woman who was suffering from typical pemphigus vegetans, the eruption being comparatively mild, and all the symptoms had almost disappeared when the patient grew worse and died. No special reason for her death was apparent.

Phagedenic and Serpiginous Ulcers, and Infective Granulomata.—Dr. William F. Breakey of Ann Arbor, Mich., reported a case of this kind occurring in a man of 26, who presented himself with a large, superficial serpiginous ulcer on the posterior surface of the right thigh. Beginning in an inguinal bubo, the phagedenic process had been going on in one direction, while repairing in others, for over six years, burrowing under the skin as it extended, and leaving patches of scar tissue blending with normal integument over a large part of the hip and thigh. The condition had been treated for syphilis, lupus, and tuberculosis.

Dr. Hermann G. Klotz said that in former years he had had occasion to treat a number of these indolent buboes. The majority of them appeared in men with chronic gonorrhea, and the possibility of the presence of the gonococci in the tissues in these cases should always be borne in mind.

Report of Three Cases of Tuberculosis of the Skin.—Dr. T. C. Gilcrist of Baltimore, Md., reported a case of (1) primary tuberculosis cutis of the sole of the foot; (2) *Erythéme induré des scrofuleux* (Bazin), accompanied by subepidermal tuberculous abscesses on the body; (3) a case of the folliclis type.

Dr. Schamberg thought that the vast majority of localized tubercular skin lesions were due to direct external inoculation and did not give rise to any systemic infection. Occasionally, however, systemic infection did occur. Cases of localized tuberculous infection upon the hands and elsewhere were numerous, and such lesions might remain innocuous for many years.

Infectious Dermatitis Gangrenosa.—Drs. Grover W. Wende and Charles A. Bentz of Buffalo, N. Y., reported such a case occurring in a man seventy years old. The condition was an infectious gangrene, first shown by a bullous eruption, changing to necrosis, variable in distribution and extent, and apparently originating through autoinoculation from a chronic leg ulcer. There was an absence of constitutional symptoms during the development of the skin lesions, but there was a secondary general infection and death from septicemia. In the bullæ and the gangrenous lesions, as well as in the internal organs at the autopsy, were found streptococci, staphylococci, diplococci, and bacilli.

The final session of the Association was devoted to the presentation of patients at the Lakeside Hospital.

A Medical Sherlock Holmes.—It is related of Dupré, Professor of Medicine at Montpellier, that seeing a soldier wearing a bandsman's uniform who had just been admitted under his care with bronchitis and emphysema, he asked a student what the man was suffering from. The student could offer no opinion, whereupon the Professor exclaimed: "My dear fellow, don't you observe the barrel-like chest and the typical respiration? It is a case of mechanical emphysema, caused by blowing the trumpet." Then, addressing the patient, he said, "What instrument do you play, my man?" To which the reply was, "The bass drum."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held September 24, 1906.

Dr. Floyd M. Crandall in the Chair.

Nomination of Officers, Censors, and Delegates.—The nomination of officers and censors for the ensuing year, and of eighteen delegates to the State Society to serve for two years, and seventeen delegates to serve for one year preceded the scientific session.

The Municipal Supervision of Typhoid Fever.—Dr. Shirley E. Sprague gave a résumé of the work as carried out by the Department of Health of the City of New York. After describing the methods adopted by the Department for recording typhoid fever cases, the maps upon which all living cases were plotted, colored tacks used to denote the locality in which the patient lived, and also the sources of infection, he stated that from January 1, 1906, up to September 12, there had been 928 cases reported. During the week ending September 8 the greatest number of cases occurred, 81 in all, while during the week ending June 5 there were only five cases. The greatest number of deaths occurred during the week ending August 25, twenty-three being the total. Up to July 14 the number of living cases reported did not exceed twenty. This showed the disease to be most prevalent during the latter part of summer and beginning of autumn. Of all the cases reported a large per cent. were residents of tenement houses, and mostly house workers. The Department examined the blood and urine in over 80 per cent. of the cases reported; in 50 per cent. of the cases the Widal test showed positive and in 33 per cent. the diazo. In the majority of the cases the spleen was enlarged and rose spots were present. Water was shown to be the cause in nearly 34 per cent., and next in order were the cases where the cause was milk, figuring 25 per cent., while oysters were the least, 5 per cent. The number of patients that contracted the disease out of town closely touched 30 per cent.; very few occurred from other members of the family, 6 per cent. being the total. Bacteriologists practically discouraged any hope of finding the typhoid bacillus in samples of water, and better results were obtained by chemical analysis, showing contamination with sewage, and also by investigation of the surrounding country whence the city obtained its water supply. The city was constantly protected by frequent inspection of its watersheds for miles around, specimens of water being repeatedly examined. The inspectors constantly inspected all stores where the cause of typhoid was traced to milk, and, when necessary, the locality from which the milk came. He believed that bathers in and around New York were one of the most dangerous sources of infection, and were among those most exposed. From a view of the statistics it seemed probable, under the present condition of water supply, that from 1,500 to 2,000 cases of typhoid fever would continue to occur yearly in the Borough of Manhattan. This number would, in all probability, not be sensibly decreased until there was installed a modern filtration system as had been strongly and ably urged by our present Commissioner, Dr. Thomas Darlington.

The Diet in Typhoid Fever.—Dr. Morris Manges said that his own views had already been expressed so fully (Medical Record, January 6, 1900, page 1) that he would restate them only briefly. During the first week the diet was necessarily a restricted liquid one, consisting of milk with its various modifications and additions, soups, broths, and soup juices. So soon as the diagnosis was certain he allowed the patients to make their own beef juice by chewing thick pieces of soft, juicy sirloin steak, the nurse standing by and not giving another piece until the patient had returned the piece that he had been chewing. This not alone kept the mouth clean, but the free flow of saliva both directly and reflexly stimulated the gastric juice. This was always keenly relished by the patients. If the patients

tolerated what was given and wanted more nourishment, ice cream, cup custard or strongly cooked rice pudding, farina, blanc mange, wine jelly, apple sauce, milk toast without the crust, or softened crackers offered a diet from which selection might be made according to the desire of the patient. If the tongue kept clean and the abdomen soft, and the stools did not contain undigested food, one might add little raw or soft-boiled eggs or scraped beef, or minced lean beef. In cases of persistent vomiting it was best to suspend all nourishment for a time, rectal feeding being relied upon to supply the food for twenty-four or thirty-six hours. All articles of food must be thoroughly cooked, or carefully minced, and as sterile as possible. The freer diet must not be given to all patients. If the patient desired more food the quantity and variety might be safely increased. In a former paper he called attention to the possibility of high fever, delirium, and other nervous symptoms of some patients being due to inanition. Rectal feeding had not received the attention it deserved, and he had found it of great aid in supplying nutrition in cases where feeding through the mouth was contraindicated. He closed his paper by stating that the reports from the various clinics were now sufficiently large to warrant some definite conclusions, and were so well shown by Dr. Kinnicutt that he felt that he could not do better than to quote his statistics: Under a liberal diet there were 733 cases, with forty-eight relapses (11.38 per cent. on a basis of 325 cases), 35 cases of hemorrhage (4.77 per cent. on a basis of 733 cases), 10 cases of perforation (1.36 per cent. on a basis of 733 cases), 60 deaths (9.47 per cent. on a basis of 633 cases). Under a fluid diet there were 4,654 cases, with 507 relapses (10.89 per cent.), 411 cases of hemorrhage (8.83 per cent.), 111 cases of perforation (2.40 per cent.), and 491 deaths (10.55 per cent.). Dr. Manges' own experience had been such that he was fully convinced that in patients who had been fed more liberally the course of the disease had been so much more favorable, the duration so much shorter, and the complications so few that he felt justified in continuing its use and recommending it to others.

The Bath Treatment of Typhoid Fever in Private Practice.—Dr. Simon Baruch presented this communication (see page 601).

Dr. Charles E. Nammack said that the first idea in the management of typhoid fever that presented itself to him was that it was more important to study what kind of a patient had hold of the typhoid fever than it was to study the fever that had hold of the patient. There was no treatment of typhoid fever *per se*. One could not have any treatment of a disease that entered the blood and became implanted in the patient. The belief that typhoid fever was an intestinal disease and could be met by intestinal measures was fallacious. The second idea that should be kept in mind was that the teeth constituted the first digestive organ and the saliva the first digestive fluid; therefore, any article of diet should receive the attention of both the teeth and saliva first. The third idea he wished to present was that certain substances that were solid outside the body became fluid in the process of digestion, and *vice versa*. These ideas he presented were fundamental principles in the management of patients with typhoid fever. So far as the treatment of this disease by baths was concerned his own experience made him believe that the bath treatment was the greatest advance made in the treatment of typhoid fever during twenty-five years that he had been fighting the disease. The use of drugs should only be according to symptomatic indications, and varied with every case.

Dr. Walter Mendelson said the keynote of the papers read was that one must treat the patient and not the disease; routine treatment could by no means be relied upon, especially in private practice. He preferred the liberal diet, giving patients other food than milk, although milk was the mainstay. The desires of the patient could by no means be disregarded, and he was made more comfortable when on a liberal diet such as cereals, meat juice, chopped meat, or ground-up meat, fruit juices, eggs, etc. When these were used he had never regretted it. The after-treatment of typhoid fever patients was important, and it was his habit to tell patients that they would not be really well for one year at least. The only after-treatment of typhoid fever patients was *rest*.

Dr. Russell Bellamy called attention to an apparatus which permitted placing the patients into the baths without disturbing them. The necessity for greater gentleness in the handling of these patients was learned by him when an interne in the hospital; so much roughness was used that he decided that the mortality could be greatly reduced by some such apparatus as he advocated which permitted of great gentleness in the use of the bath.

Dr. Charles G. Am Ende said that inasmuch as typhoid fever was caused by an invasion of Eberth's bacilli first into the intestinal tract, and thence into the general circulation, their extinction implied arrest of the disease and its cure. These he had obtained by the use of quinine in sufficiently large quantities, counteracting its depressing effect by sweet spirit of nitre. Capsules containing five grains of quinine and one-half of one drop of creasote were given to adults seven times and sweet spirit of nitre three times a day; to children less in proportion until recovery. On the third or fourth day general improvement in the mental and other conditions was manifested, a voracious appetite developing a few days later. In one case, which he reported, the entire disease had disappeared on the tenth day of treatment. The longest case under this treatment lasted twenty-one days, and this was because it was associated with a capillary bronchitis. He did not find it necessary to resort to baths.

New Constitution and By-laws.—The new constitution and by-laws were presented to the society and will be acted upon at the October meeting.

Spontaneous Rupture of Hydatid Cysts of the Liver Into the Peritoneum.—Tremblin in his thesis states that the spontaneous rupture of hyatid cysts of the liver into the peritoneum is relatively frequent since it has been shown according to recent statistics that this occurs in more than one-fifth of these cases. The symptoms consist of a sensation of internal laceration, disappearance of the hepatic tumor, ascites, and urticaria. In certain cases, some of these signs fail, but the urticaria is almost always present. The complications are numerous; among these are sudden death from hydatid intoxication or from peritonitis, and subphrenic abscess. Diagnosis is relatively easy. Examination of the blood shows an abundant eosinophilia. Anatomical researches will reveal the nature of the peritoneal fluid and will assist the recognition of secondary lesions. The treatment of choice is laparotomy. As soon as the diagnosis is established, operation is indicated.—*Gazette des Hôpitaux Civils et Militaires*.

Two Tumors of the Breast in Men.—V. Cornil and V. Campenon report these cases. The first patient was a man fifty-seven years old. In 1898 he first noticed a growth as large as a pea near the nipple. The tumor grew to the size of a pigeon's egg. It was not until 1905 that the growth ulcerated. It increased in size, and operation was performed. Histological examination showed it to be an epithelioma. The second patient was a man forty-eight years old, inclined to obesity. In September, 1905, a puppy bit him on the right breast without making a wound. He suffered sharp pain, which disappeared at the end of a few days. In December the pain returned. The tumor increased in volume. At operation the entire breast was removed. The tumor consisted almost entirely of fibrous tissue and was shown to be a fibroma or cystic fibroadenoma.—*Bulletins et Mémoires de la Société Anatomique de Paris*.

New Instruments.

AN IMPROVED ELECTRIC OPHTHALMOSCOPE.

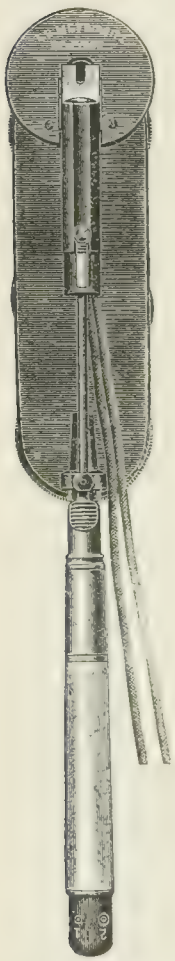
By WILBUR B. MARPLE, M.D.,

NEW YORK.

OPHTHALMIC SURGEON, NEW YORK EYE AND EAR INFIRMARY, ETC.

In presenting this model of an electric ophthalmoscope, I want to say that it is Dr. Dennett's ophthalmoscope with two or three modifications, but these modifications—at least in my hands—make it a very much more useful instrument.

The difficulty I found in using Dr. Dennett's instrument—and this is true also of De Zeng's—was that I did not seem able to direct the illumination always to that part of the fundus at which I wanted to look. Especially was this true if I endeavored to examine anything at the lower part of the fundus. I could always observe a horizontal line of shadow, beyond which I could not see, turn the instrument howsoever I might. For example, if I wanted to investigate the periphery of the lens below, to ascertain as to its transparency, I would invariably find this region in total shadow. I discovered, however, that if I held the ophthalmoscope with the handle directed horizontally to the side of the patient, then I could illuminate the lower part of the fundus all right. It was evident that the trouble was that the whole mirror was entirely below the line of vision when using it. I then began experimenting with various forms of mirror, the first shape being one with a round aperture, like the ordinary ophthalmoscope. But so much light was reflected into the observer's eye by such a mirror, of the ordinary thickness, that a very unsatisfactory view of the fundus was obtained. My nephew, Professor of Physics in the University of Wisconsin, then sent me a very thin mirror, hoping that the reflection would be less from this, but I could see no practical difference. As the reflection was entirely from the upper edge of the aperture, I next cut this part of the mirror away, using a U-shaped piece of glass. With this there was no annoying reflection, and to my great satisfaction I now found that the whole fundus was illuminated, and also that I could control my illumination completely, investigating the lower part of the fundus as well as any other. To satisfy myself I covered the two arms with blackened paper and again found the bottom of the fundus in darkness. I then uncovered more and more of the two arms until I found just the length which gave me what I wanted, and the mirror seen in the instrument shown here is the one which gives me the best results. (See figure.)



There is one other feature to which I wish to call your attention, and that is the movable lamp. Dr. Dennett's latest modification has an arrangement by which you can use the lamp in two positions. But it occurred to me that it would be an improvement if the position of the lamp could be controlled by the examiner *while using the instrument*. So I accordingly had an arm carried down with a small roughened knob at the end, by which the observer, when examining a patient, can slide the lamp up and down and thus get just the kind of light which best brings out what he is looking for. One has only to use this modification once to appreciate what a great advantage it is.

It was my desire, in taking up this subject, to see if I could not get an instrument which I would use not merely when I could not use the ordinary instrument, but always. I can only say that I now rarely use anything else in my office. It is equally useful in the indirect as in the direct image. In the detection of fine opacities in the media, using the movable lamp, it is far better than the ordinary reflecting ophthalmoscope. I have had it put on my Morton ophthalmoscope, but it can be put on any instrument which any individual is accustomed to use. There is a slight defect in the illumination of the fundus corresponding to the small defect in the mirror above, but this is of very little importance, as a slight movement of the instrument brightly illuminates the part which was previously somewhat shadowed. I use the street current and a rheostat in my office, but when this is not present this little dry-cell battery is very satisfactory and is one I have used for a couple of years, at the bedside of patients, at their homes. When working with the rheostat in my office I can readily vary the intensity of the light while examining the patient, by pushing the rheostat slide in one or the other direction. This is a very great advantage.

As explained above, the lamp is moved up and down while using the instrument by means of this little knob (See figure), held between the thumb and index finger. I shall have the wires fastened to the body of the instrument, so that a pull on the wire, which sometimes occurs, will not move the lamp. To change the lamp, if burned out, unscrew the small screw which you see, and the movable arm, with lamp at the end, can then be pulled clear out, when you can unscrew the burned-out lamp and put on a new one.

To use in the indirect image, hold at the usual distance for working with the inverted image; then move the rod with the lamp at end until the flame (or reflection of this) on the patient's forehead is a long, narrow bar of light; then interpose your lens, and a good inverted image of the fundus is obtained.

In the use of the ordinary reflecting ophthalmoscope the most difficult thing to learn is the management of the illumination, and to master this thoroughly takes long practice. In my electric ophthalmoscope the illumination takes care of itself, and this renders it especially useful to the medical man, not an ophthalmologist, who has occasion to use an ophthalmoscope. One of our most prominent neurologists, to whom I showed the instrument in my office, was so delighted with the facility with which he could use the instrument that he has employed it in his office ever since.

We are, of course, partial to our own devices, but I have had several of my confrères here and in Philadelphia try my ophthalmoscope, and they are all as enthusiastic over the instrument as I am myself. So that I am quite sure that if any one will give it a fair trial he will appreciate its many advantages and, like myself, will feel that it is something he cannot be without.

I am indebted to Mr. E. B. Meyrowitz, by whom

*Presented to the American Ophthalmological Society at its meeting in New York City, June 28 and 29, 1906.

the instrument is made, for many courtesies in carrying out my suggestions. As stated above, my electric attachment can be put on any form of ophthalmoscope to which the individual is accustomed.

46 West Fifty-third Street.

Therapeutic Hints.

Chronic Gastritis.—

℞ Acidi salicylici.....gr. xxiv
Oleoresinæ capsici.....gtt. vi.

Action of the X-Ray on the Ovary of the Dog.—Roulier in his experiments on three dogs has met with negative results. The ovaries presented no lesion either macroscopically or microscopically. In the case of rabbits, however, Roulier has obtained results conforming in all points to those of previous observers. He concludes that the *x* ray has a selective action on the ovary. Atrophy may be easily obtained in very small animals without the production of alopecia. In the dog, it is very difficult to obtain in spite of the production of severe lesions of the skin.—*Gazette de Hôpitaux Civils et Militaires.*

Surgical Suggestions.

Chylorrhea during or following operations on the neck, according to von Graff, is always due to injury to the thoracic duct. Ordinarily this accident causes only temporary interference with nutrition, although in the presence of other complications, such as severe hemorrhage during the operation or protracted narcosis, it may lead to death. The only effectual immediate treatment consists in ligature of the thoracic duct or suture of the injury, and this should be done either at once or as soon as possible as a secondary operation. Ligature of the thoracic duct in the neck entails no danger and the treatment of chylorrhea by packing should be carried out only when ligature of the duct cannot be performed owing to technical difficulties.—*Wiener klinische Wochenschrift*

In Breech Extractions Wienskowitz recommends as a tractor a piece of rubber tubing with a webbing foundation. This is less likely to injure the fetus or the maternal soft parts than the hook, and is much easier to carry around the fetal thighs than the cord fillet. A piece about three-fourths of a yard in length and one-half inch in diameter is used, after having been sterilized by boiling.—*Zentralblatt für Gynäkologie.*

The Fetal Heart Sounds may, according to Schwab, be rendered more easily audible during the early months of pregnancy by the following maneuver: Standing at the right side of the patient, the right hand with its ulnar border downward is placed just above the symphysis and is pressed directly backward until the uterus with its contents can be forced upward toward the umbilicus and firmly fixed in this position. The stethoscope is then applied over the most prominent portion of the mass.—*Zentralblatt fur Gynäkologie.*

Gunshot Wounds of the Abdomen.—Stated in the order of their fatality, military surgeons of the widest experience have set down the following list for gunshot wounds of the abdomen: 1. Wounds of the spleen are the most fatal of all. 2. Perforating wounds of the small intestine and mesentery. 3. Wounds of the stomach. 4. Wounds of the large bowel. 5. Wounds of the urinary bladder. 6. Wounds of the liver. 7. Wounds of the kidney. 8. Nonperforating wounds of the intestine.

Neuralgia and Sciatica are treated by Kuester by intraneural injections of a 50 per cent. antipyrine solution. From 0.2 to 0.3 c.c. of the solution is injected directly into the trunk of any of the smaller nerves, while larger amounts are used for the sciatic nerve. The injections are repeated at intervals of eight days and from three to five are usually needed. In some cases the curative effect is manifested only some weeks after the cessation of treatment.—*Zeitschrift für aerztliche Fortbildung.*

A New Method of Gastrostomy.—Tavel suggests the following procedure as a means of avoiding many of the inconveniences attending the usual gastrostomy opening. Through a median incision a portion of the jejunum about 15 cm. in length is resected without interfering with its mesenteric attachments. The continuity of the intestine is restored and the distal end of the resected segment is sutured into the stomach opening after having been passed through the mesocolon and omentum as in gastroenterostomy. The proximal end is carried to the surface and is implanted in the abdominal wall, preferably in a separate incision. Tavel has carried this operation out in one case with excellent results, there being no leakage even on coughing or on exertion. The only disadvantage of the plan is the extra time required to carry it out.—*Zentralblatt für Chirurgie*

For Contracted Pelves Credé proposes a plastic operation intended to secure a permanent increase in the pelvic diameters. A semicircular incision is made over the symphysis rather more on one side than on the other. The pubic bone is laid bare and after the ordinary pubiotomy a quadrilateral piece is excised from the horizontal ramus by means of a Gigli saw carried through the obturator foramen. This piece of bone is then wedged into the gap caused by the pubiotomy. Credé has performed the operation on one patient during labor, but he states that it is intended primarily for use during the early stages of pregnancy. The true conjugate is in this way permanently increased from 1 to 1.5 cm.—*Zentralblatt für Gynäkologie.*

Hyperidrosis has been successfully treated by the application of the *x*-rays, and it has also been claimed that color may be restored to gray hair in the same way.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 6, 1906:

	Cases	Death
Tuberculosis Pulmonalis	346	154
Diphtheria	100	22
Measles	30	2
Scarlet Fever	49	3
Smallpox		
Varicella	11	—
Typhoid Fever	121	25
Whooping Cough	32	15
Cerebrospinal Meningitis	12	11
Malarial Fever		
Totals	800	232

A Few Words for the Rights of the Prostate.—James W. Henson believes that every man with symptoms of prostatic hypertrophy, if an examination proves this condition to be accompanied by residual urine of five or even four ounces, should be advised in positive terms to submit to a radical operation, whether infection be present or not, unless such an operation be contraindicated by an enfeebled general condition from the results of obstruction and infection or some other cause. The reasons given for this advice are first because infection will be established whether the catheter be used or not, and the use of it only hastens infection. Next, the surgeon cannot keep daily track of the progressive daily pathological changes and be able to tell just when that point in these changes is reached, beyond which the bladder will not recover its function if given a chance. The third reason given by the writer is that in cases taken early a radical operation which thoroughly and successfully removes the obstruction results in a cure. Finally, the mortality in early operations and in good hands is low. The writer believes that it is safer for each operator to cling to that method with which he is best acquainted, and by which he feels sure that he can do what is requisite with the least expenditure of time. The writer adds that for patients who are too feeble or too far gone from infection to stand any radical operation, drainage by a suprapubic or perineal cystotomy affords much relief. Some of these cases, indeed, become candidates later for radical operation.—*The Mobile Medical and Surgical Journal.*

Syphilis Hereditaria Tarda; Report of a Case.—Louis M. Warfield had under his care a boy eleven years old who complained of catarrh of the head and swelling of the neck. The mother had had three miscarriages. She told a rambling story of how the boy nearly lost both eyes from inflammation after an attack of "malaria." The boy became gradually better, although it was two years before he could distinctly recognize objects. During that period he suffered with headache. About a year ago, one day, he spat out a piece of bone. Difficulty of breathing through the nose, from which he had suffered for some time, became worse and he became deaf in both ears. About two weeks ago another piece of bone came from the "back of the throat." Since then the bridge of the nose has been swollen, red, and very painful to the touch. About a year ago the boy's neck began to swell. The anterior nares are small and covered with crusts. The bridge of the nose is somewhat flattened. The patient says that it seems as if there were a skin over the eye. He has Hutchinsonian teeth. In the hard palate are two slitlike perforations through which a small probe can be passed to the nasal cavity. Farther back near the small palate is a small perforation large enough to admit the tip of the little finger. The patient hears with difficulty. The lymph nodes on both sides of the neck and beneath the chin are markedly enlarged. The diagnosis was made of hereditary lues and appropriate treatment was advised. If the history is correct, the child showed absolutely no symptoms of the disease until the seventh year. The writer thinks that the history of miscarriages in the mother shows that this case is one of late manifestation of hereditary lues and not one of acquired lues.—*Archives of Pediatrics.*

Bile Poisoning.—Woodbridge Hall Birchmore calls attention to the fact that "uremia" is a disorder secondary to bile poisoning. Bouchard has shown by direct experiment that a highly jaundiced urine is more toxic than the same urine after removal of its coloring matter in the proportion of 30 to 13. Jaundice is commonly met with in two forms, the yellow and brown; in some cases "green jaundice" has been noted. The coloring matters which have been isolated may be called "bile yellow," "bile green," and "bile red." Bile yellow is the pigment first abstracted by the connective tissue and epithelial tissue cells. It is the one which first stains the liver. It may be said in general that whenever the liver excretion is so interfered with as to cause the bile to enter the blood, this yellow tint at once appears in the skin. Various color changes take place in these pigments, the details of which have not yet been mastered. Symptoms of poisoning do not take place while the skin is pigmented, or while the urine is highly colored, but while the urine, whatever be its hue, is colored but little. This fact is of great clinical importance. Without any doubt, the desire to escape is the basal impulse of all the strange vagaries of those suffering from the bilious intoxication. The "mania of depression" sometimes ends in suicide. The large majority of these patients in whom there is every evidence of temporary insanity may be restored by ridding them of the bilious intoxication. Examinations of many of these patients showed the blood to be loaded with bile derivatives; none of the patients was jaundiced. The evidence of bile must be looked for in the blood where it can do the utmost mischief and yet give no visible and objective sign. The pigment in the blood most to be dreaded is the bile-red. Great responsibility in these cases rests upon the family physician and he should always be on the lookout for danger.—*Medical Examiner and Practitioner.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending October 5, 1906:

ANGINA PECTORIS: ITS MECHANISM AND TREATMENT.

BY FRANCIS HARE, M.D.,

LONDON, ENGLAND.

LATE CONSULTING PHYSICIAN, BRISBANE GENERAL HOSPITAL.

IT is a fundamental physiological fact that during life the general or aortic blood pressure tends to be maintained at an approximately uniform mean height; and this in spite of the fact that countless and ceaseless variations of caliber are occurring in all parts of the vascular system. It follows that "every variation in one part is compensated by a simultaneous and contrary variation in another part" (Leonard Hill[1]). In less general terms, vasoconstriction in one part is being constantly associated with, and therefore compensated by, vasodilatation in another part, and conversely. But the uniformity of aortic or general blood pressure thus in great part secured is obviously attained at the expense of uniformity of localized blood pressure. For it is certain that the local blood pressure peripheral to the vasoconstriction is reduced, and that the local blood pressure peripheral to the vasodilatation is increased. Less technically put, the blood stream is in great part shut off from the constricted areas, and turned on with concentrated force and in larger quantity to the dilated area. Thus there occurs in the latter what may be conveniently termed "vascular distention."

Vascular distention varies widely in degree and in localization. It may be physiological. There seems little doubt that on exposure to cold sufficient to cause shivering there is some vascular distention of the muscular area, and that this depends upon dilatation of the muscular arterioles correlative of constriction of the cutaneous arterioles. There is no doubt that after food there is vascular distention of the digestive organs, and that this depends upon vasodilatation localized therein and upon correlative vasoconstriction elsewhere, especially perhaps in the skin. And many other examples of physiological vascular distention could be given.

But vascular distention of essentially similar mechanism is a common and important factor in the domain of pathology also. Its symptoms and signs will, of course, vary with the locality and nature of the tissue affected. If the tissue affected is vascular and well supplied with nerves, but prevented by rigidity of its surroundings from freely expanding, there will be pain from nerve pressure. If, on the other hand, there is room for expansion as on a free surface, there may be an absence of pain, but there will probably be symptoms or signs due to the increase in bulk of the tissue. Elsewhere[2] I have brought forward a considerable amount of authenticated evidence in support of the view that both the pain of migraine (not to mention many less formal headaches) and the dyspnea of asthma, depend essentially upon vascular distention, the former of the scalp or membranes of the brain, the latter of the mucous membranes of the bronchioles, and that in both cases such vascular distention depends upon vasodilatation more or less localized, and upon vasoconstriction more or less generalized.

Now, it is a fact that both migraine and asthma have strong affinities with angina pectoris. The three paroxysmal affections are prone to alternate, not only in the family, but in the personal, history of the patient. A patient may have migraine or asthma for years, lose his accustomed paroxysm either suddenly or gradually, and concurrently commence to suffer from angina, or conversely. Again, cases have been observed which partake of the characters of any two, or all, of these neuroses.* It is true that the affinities of the paroxysmal neuroses have slipped somewhat into the background of medicine during recent years. That is due, doubtless, in part to the strictly inductive spirit of modern inquiry, which concerns itself mainly with the antagonisms of disease, but also in great part to the overgrowth of specialism.† But the affinities referred to are all described in the works of those less specialized physicians who wrote in the middle period of the nineteenth century, and they are conspicuous to-day for those who are accustomed to take a comprehensive survey of disease.

Further, the three named affections conform in several of their objective signs. In all there is an increase in peripheral vasoconstriction. This is well recognized in the case of angina; its observation, of course, led directly to the use of amyl nitrite. Though less frequently mentioned in text-books, an increase in peripheral vasoconstriction will be found to be equally constant in both migraine and asthma. The small pulse of migraine has been noted by Austie,[3] Lander Brunton,[4] William Russell,[5] and others. The small pulse of asthma has been noted by Hyde Salter,[6] who points out that it is invariable, and is "small in proportion to the intensity of the dyspnea." It has also been noted by William Russell.[7] Many writers have pointed out the bloodlessness and coldness of the skin, most marked in the extremities, of both affections.

In the case of migraine, the more or less localized compensatory vasodilatation and consequent vascular distention has been noted by Möllendorff,[8] Wilks, and others. In the case of asthma, the same condition has been assumed by Weber, Andrew Clark, Osler, and all who accept a vasomotor explanation of this affection. But in the case of angina, no one so far, as I can discover, has hitherto entertained

*I have given many examples of these alternations and mixed neuroses in a recent work, "The Food Factor in Disease," Longmans, Green & Co.

†I have recently come across the case of a lady who suffered from asthma, hay fever, anginal seizures, and eczema, for which affections she was attending at the same time a physician known for his skill in lung diseases, a rhinologist a physician eminent in heart affectfons, and a dermatologist.

an analogous view. Yet analogical considerations consistently point to such a conclusion.

Accordingly, we may frame the following hypothesis: The pain of angina depends upon *vascular distention in the mediastinum,* which vascular distention is the result of a more or less localized vasodilatation and of a more or less generalized peripheral vasoconstriction.

Here it would seem necessary to state that nothing which has been said hitherto in this paper is to be regarded in the light of proof of this hypothesis; all that has preceded is merely suggestive. The proof of this, as of all hypotheses which are insusceptible of direct experimental demonstrations, must rest upon the number of accredited observations on the natural history of the disease, which it is capable of correlating and explaining—in short, upon the extent of its consistency with known facts.

Vascular distention affecting the walls of the heart, especially the coronary areas, and the coronary and cardiac plexuses, would fully explain both the characteristic precordial pain of angina and the various radiations of that pain. The coronary arteries are relatively large; the heart muscle, for a muscle, is peculiarly close in texture, and the capillaries are "very numerous and closely arranged."[9] Swelling to any extent would probably be precluded, tension would be great, and therefore nerve structures would be exposed to extreme pressure. The number and extent of the communications of the nerve plexuses affected would sufficiently account for the wide variations of the pain experienced. Furthermore, frequently recurrent vascular distention would explain the inflammatory changes demonstrated in the cardiac plexus by Lancereaux and Huchard, and the right and left coronary plexuses by Mott.[10] The neuritic changes would be the result, not as has sometimes been assumed, the cause, of the anginal seizures.

But, in order to appreciate fully the extent of the consistency of the hypothesis formulated, it is essential to grasp firmly all the factors in the mediastinal vascular distention. These are obviously four in number: (1) The localized vasodilatation; (2) The generalized peripheral vasoconstriction; (3) The work done by the left ventricle, and (4) The integrity of the mitral valve.

1. *The localized vasodilatation.* This, in all probability, affects mainly, if not solely, the coronary arteries. This assumption is consistent with Schäfer's recent demonstration that these vessels are unprovided with vasomotor nerves. The vessels probably undergo dilatation passively through the rise of general blood pressure resulting from the generalized peripheral vasoconstriction. It is unnecessary to point out that Schäfer's demonstration, if confirmed, must prove fatal to the view that the pain of angina depends upon "intermittent claudication" of the coronaries.

As is well known, atheroma of the coronaries is one of the most frequent lesions found postmortem in fatal cases of angina pectoris. Herewith the assumption of vasodilatation is consistent. Intravascular strain, which is especially prone to occur in dilated vessels, is admittedly one of the commonest factors of arterial disease; but here, again, the disease would be the result, rather than the cause, of the anginal seizures. The same factors are seen to be at work in some cases of old-standing migraine and supraorbital neuralgia, in which arteriosclerosis of the corresponding temporal artery has followed the long recurrent vasodilatation associated with those neuroses (Gowers,[11] Thoma[12]). And there is "evidence to show that arteriosclerosis can be brought about by section of nerve trunks (Fraenkel, and others[13])." Such an injury would cause prolonged vasodilatation. Consistent with the view of vasodilatation and ultimate disease of the coronaries from intravascular strain, is the recent discovery by Arthur Morison of a small but fully developed coronary aneurysm in a case of fatal angina.[14] The aneurysm had distended the intima and was lying in contact with, and pressing upon, the middle or muscular coat of the artery.

2. *The generalized peripheral vasoconstriction.* Obviously, this factor is as responsible for the mediastinal vascular distention as is the localized vasodilatation. Through its means the blood stream is in great part shut off from wide areas, and turned on with concentrated force and in larger quantity to the dilated area. Its responsibility may be shown in many ways. Everything which tends to increase peripheral vasoconstriction tends to induce anginal paroxysms, and everything which tends to relax peripheral vasoconstriction tends to relieve anginal paroxysms.

In Nothnagel's cases of so-called "functional" angina, "the attacks were . . . definitely traceable to external cold, and were relieved by hot foot baths and frictions." Further, "the earliest and most conspicuous symptoms . . . were coldness and pallor, with numbness and stiffness of the limbs; the palpitation, the feeling of oppression at the chest, the giddiness, the sense of impending death, being all secondary" (Hilton Fagge[15]).

The immediate relief usually afforded by amyl nitrite inhalation, by hot alcoholic drinks, ether, etc., is of course fully explained by the relaxation of the peripheral vasoconstriction. In many of my cases, some of them advanced in life and suffering from organic heart complications, the application of hot foments to the chest, back and front, has given instant and complete relief. In some, sipping hot water has acted similarly.

On the other hand, the hasty swallowing of cold water will, according to Fagge,[15] induce a paroxysm in some cases. And digitalis, a drug which increases peripheral vasoconstriction, as well as the strength of the systole, has been shown to act injuriously in some cases of angina. Dr. A. Elliott describes a case of mitral stenosis with severe anginal symptoms in which digitalis, when given persistently, was always followed by fresh attacks of angina.[16]

Sudden emotion, such as fear, is prone to be associated with marked cutaneous vasoconstriction, and Clifford Allbutt has shown that fear may bring about a very measurable rise of blood pressure.[17] Conformably, the influence of fear in precipitating anginal seizures is notorious.

George Oliver has shown that a rise of blood pressure sets in after meals, attaining its maximum in about an hour;[18] this he ascribes in great part to peripheral vasoconstriction—a vasoconstriction which has been quite recently referred to by William Russell[19] as an "arterial abdominal reflex." Terms are, however, of relatively slight importance in this connection. What is important is to recognize that normally peripheral vasoconstriction is increased during the period of digestion and absorption. For, during those processes, there is admittedly an exaggerated tendency for the development of anginal paroxysms. This statement hardly calls for confirmatory quotations.

The marked cutaneous vasoconstriction associated with malarial rigors is evident, and many cases are recorded in which anginal paroxysms have complicated, or been substituted for, malarial rigors.[20]

Oliver has observed that during the menstrual

period the caliber of arteries, *e.g.* the radial, ceases to respond to changes of posture; this phenomenon he regards as due to transitory vasoconstriction.[21] According to Giles, the increase of vascular tension is greatest on the day preceding, and the first two days of menstruation.[22] Hence, it is not surprising to find that anginal seizures are especially frequent at this time, and usually cease when the flow has become well established. The same is true of migraine, of asthma, and indeed of practically all the vasomotor neuroses.

Physical exercise has a two-fold influence on blood pressure. During the first ten or fifteen minutes it causes a rise, thereafter a fall (Leonard Hill[23]). Now, whatever the cause of the initial rise, there is no doubt whatever that the subsequent fall is due to the large vasodilatation, which occurs in both the muscular and cutaneous areas. It follows that exercise would produce an exactly parallel increase and decrease in the mediastinal vascular distention of angina, and this is entirely consistent with clinical observation on the effect of exercise in anginal subjects. Fagge says: "It is . . . a curious fact that some persons, after being pulled up by the pain three or four times at the beginning of a walk will afterwards go on with ease for several miles."[24] The fact is common—I had almost said invariable—in all such anginal patients as take physical exercise. It occurs also in asthma and many other vasomotor neuroses, and would be better appreciated were a larger share of professional attention devoted to personal life histories and subjective symptoms.

3. *The work done by the left ventricle.* Obviously, this is an essential factor in the maintenance of vascular distention wherever situated. *Whatever reduces the work will reduce the distention, and vice versa.* Now, the work done may be reduced in many ways. It may be reduced temporarily by vague inhibition of the heart beat. This happens in many cases of ordinary syncope, and there can be little doubt that such inhibition is secondary to peripheral vasoconstriction; otherwise there would be no explanation of the marked and instantaneous action of amyl nitrite inhalation in most cases of syncope. The same may be true of the vague inhibition which occurs in many cases of angina; or it may be that here the inhibition depends upon the pain. At any rate, cases are not very rare in which syncope and angina alternate, and there are some in which syncope supervenes during a paroxysm of angina. In the latter case the supervention of the syncope is contemporaneous with the cessation of the pain, and either may be at once terminated by amylnitrite inhalation, or heat applied externally over an extensive area. In all such cases it is reasonable to believe that the cardiac inhibition responsible for the cerebral anemia of syncope relieves the mediastinal vascular distention, and so terminates the pain of the anginal seizure. In other words, the syncope and the angina represent alternative modes of compensation for the common peripheral vasoconstriction.

Cardiac inhibition occurs to a marked extent in nausea and vomiting, and an emetic is a time-honored remedy in angina and in many other paroxysmal neuroses. The relief which follows is not due to the emptying of the stomach, for it may follow upon the supervention of nausea only, and even when the stomach contains no food to be vomited.

But the work done by the heart is permanently reduced in the cardiac failure of advanced cardiac disease, and Oliver has pointed out that patients long subject to precordial pain obtain permanent relief on the supervention of cardiac dilatation and failure.[25] I have seen the same occur myself in several cases, not only of angina, but of asthma also.

4. *The integrity of the mitral valve.* This factor is clearly essential for the development and maintenance of the mediastinal vascular distention. No more effectual means of precluding vascular distention of any area in advance of the aortic opening could be devised than a leak in the mitral valve, whereby much of the onward force of the blood-stream would be lost. For the vascular distention of the mediastinum there would be substituted a tendency to vascular distention of the lungs. Hence it is not surprising to learn that mitral regurgitation is largely inconsistent with anginal seizures. Broadbent has placed it on record that "the supervention of mitral insufficiency may greatly diminish the liability to attacks in cases of angina,"[26] and that the further course of the disease may be entirely changed. It may be added that exactly the same is true of asthma. I have records of two cases of old-standing asthma with emphysema in which mitral regurgitation ensued, and both of which subsequently remained quite free from the asthmatic type of dyspnea.

Manifestly, anginal seizures may be deferred or relieved by removing any of the factors of the supposed mediastinal vascular distention; they may, on the other hand, be precipitated or increased in severity by accentuating any of the said factors. It follows that the simultaneous accentuation of any two or more of these factors will exert an even more powerful influence. This is not difficult to demonstrate. For example, fear or anxiety may be combined with exposure to cold, the sudden commencement of physical exercise, and the digestion and absorption of food following a full meal. A medical man might be summoned shortly after dinner to a sudden emergency, and proceed to walk sharply up a steep hill in the teeth of a strong, cold wind while inadequately clad. There could be no more certain means of inducing a seizure in a predisposed subject. Indeed, the writer, who has no such special predisposition under other conditions, has more than once succeeded in bringing about an excellent imitation of a paroxysm in his own person in the above circumstances. There was considerable precordial pain extending along the left clavicle and into the left scapula with a sense of anteroposterior compression of the left chest, symptoms which demanded instant cessation of the exercise.

While it is thus clear that a long series of authenticated observations recorded of the affection are consistent with the theory of the mechanism of angina here formulated, I have, on the other hand, failed hitherto to find any facts which are at all necessarily inconsistent therewith.

The conclusion at which I have arrived is that the ordinary anginal seizure conforms in its mechanism to many other paroxysmal affections such as migraine and asthma, which may be referred to as "vasomotor neuroses." In all there is a more or less rapidly developing peripheral vasoconstriction, and in all there is a correlative area of vasodilatation. It follows that in each case there is some factor or factors intervening which determines the localization of the differentiating vasodilatation. These, however, require much further elucidation. If we accept Schäfer's view that the coronary vessels are destitute of a vasomotor nerve supply, we must assume that the vasodilatation in the case of angina is purely passive, and due solely to the increased resistance in the periphery. And, further, we must assume that the peripheral resistance is uncompensated, or at least inadequately compensated, either by areas of

vasodilatation in advance of the coronary area, or by vagus inhibition of the heart beat. Hence, some at any rate of the factors determining the special vasodilatation of angina would be negative factors. Amongst such we should have to include an absence of disorders like migraine and asthma—disorders which imply vasodilatation in other areas, and which consequently would tend to prevent the necessity for coronary vasodilatation.

The theory advanced is inconsistent with the view that anginal paroxysms *depend upon* organic disease of the heart walls or valves, of the aorta or the coronary arteries. But it is entirely consistent with the fact that in very many cases the paroxysmal affection occurs in the subjects of organic cardiac and aortic lesions. This statement involves no new conception. Fagge says of angina: "The long duration of the disease in some cases seems inconsistent with the idea that any of the organic lesions . . . can have existed throughout its whole course. Possibly the paroxysms of angina owe to the lesions in question their severity and and their tendency to prove fatal, but do not stand to them in the direct relation of effect to cause. For, if the disease be regarded as a struggle on the part of the heart to overcome an excessive resistance in the arteries, enfeeblement of the cardiac muscle . . . cannot but add greatly to the embarrassment of the heart and the danger of the patient."[27]

It would seem that the angina is not due to the organic lesions any more than is asthma due to emphysema, or migraine to atheroma of cranial vessels. What, then, is the connection between the organic lesions and the angina? The association is far too frequent to be explained by mere fortuitous coincidence. It may be observed that the lesions most commonly found in fatal cases of angina—atheromatous conditions of the aorta and coronary arteries, chronic valvalitis, etc.—are just those lesions which, it is now admitted, are prone to follow frequently-repeated or continued strain, and it is probable that in some cases such strain has taken place, mainly during the actual occurrence of the recurrent anginal paroxysms. But in many others this explanation fails, for the lesions are manifestly of much older date than the angina. Then it seems reasonable to me to ascribe them to the chronic peripheral vasoconstriction—one great factor in persistent high blood pressure—which so commonly precedes the development of angina, and which Huchard has shown constitutes the earliest stage (for the most part unrecognized) of many forms of chronic organic disease of the heart and vessels. In general terms, we may refer the organic lesions and the paroxysmal affection to a common antecedent cause.

Treatment.—This may be divided into (1) treatment of the paroxysm, and (2) treatment preventive of future paroxysms. 1. The treatment of the paroxysm has been almost sufficiently indicated already. Inhalation of amyl nitrite still maintains its place as the most prompt and reliable means of relief in most cases. Where this fails morphine, hypodermically, or chloroform inhalation, will usually succeed. But, in the absence of these drugs, the extensive application of heat to the surface, combined with hot drinks, will generally afford effectual relief. 2. Preventive treatment resolves itself into the prevention of exaggerated peripheral vasoconstriction, continuous or recurrent. Now, of recent years there has been an increasing tendency to regard variations in the composition of the blood as an important factor in determining peripheral vasoconstriction, whether this results in some formal vasomotor paroxysm, such as angina, or in a general increase of vascular tone, with consequent increase of blood pressure. In the malarial paroxysmal neuroses there can be no doubt as to the responsibility of the blood state.[20] But malaria does not enter into the great majority of these affections. The question arises, therefore, whether there does not exist some much commoner hemic factor in the ordinary paroxysmal neuroses. Many have regarded, and still regard, uric acid in solution as a common hemic factor. For myself, I have brought forward evidence to show that one of the commonest hemic factors in the paroxysmal neuroses is "hyperpyremia,"[28] a term which implies that the blood contains an excess of carbonaceous or fuel substances, and this evidence has already been accepted as sufficient in many quarters, notably by Professor Russell H. Chittenden. But, even assuming the responsibility of hyperpyremia as proved, there is yet another equally, if not more, important factor to be considered, namely, the responsiveness of the vasomotor system to the hyperpyemic state. This certainly varies widely with the individual. There would, therefore, be at least two distinct points for therapeutic attack, namely, (*a*) the hemic or humoral, and (*b*) the vasomotor or vascular factor.

The hemic or humoral factor. Acting on the view that uric acid is the common hemic factor, Haig and his numerous followers have treated most of the paroxysmal neuroses by means of a purin-free diet, and there is no doubt that, if in such a diet, the proportion of *purin-free proteid also* is adequately reduced, a certain measure of success will be attained. But such success is, so far as I can see, entirely consistent with the view that hyperpyremia is the real hemic factor in these cases. On the other hand, those who like myself accept the hyperpyremic theory, will pay little attention to the amount of proteid, and none at all to the purin substances, but will proceed to cut down the carbohydrates, especially the saccharine carbohydrates, and the fats. And these, too, will meet with a large measure of success, more especially as I have shown in patients who are well nourished and, above all, in the obese. Further, whichever plan be adopted, carefully graduated physical exercise, by increasing the physiological expenditure of carbon and promoting general peripheral vasodilatation, will vastly increase the success which follows the alteration of régime. Of course, in the case of angina, due regard must be paid to the existence of complicating cardiac and circulatory lesions.

But there will still remain many cases in which the result is incomplete. The carbonaceous foodstuffs may have been cut down as far as practicable; regular exercise may have been persevered with, and yet the paroxysms continue to recur, though perhaps with diminished force and frequency. In such cases it is advisable to operate directly upon the vasomotor system, with a view to diminish its irritability, especially its responsiveness to hyperpyremic conditions. Is there any therapeutic procedure which is capable of exerting a lasting inhibitory influence on the tendency to exaggerated or disordered vasomotor action? Until a few years ago I should have answered unhesitatingly in the negative. Now, however, I have reason to hope that such a therapeutic measure has been discovered, and that it is applicable to the case of angina. The marked and enduring success of the plan introduced by Dr. Alexander Francis, of systematically cauterizing the healthy septum nasi in cases of asthma, spasmodic and other, is now becoming widely known in this country and America. It has been longer known in

Australia. When I had myself succeeded in passing through the inevitable period of incredulity it occurred to me that the procedure might be useful in angina also. Asthma and angina had many factors in common; they were interchangeable, and both depended on an area of vasodilatation correlative of widespread peripheral vasoconstriction. Accordingly, I brought these views before Dr. W. N. Robertson of Brisbane, who, as successor to Dr. Francis, was then practising the nasal treatment of asthma. That was in 1904. In the *Australasia Medical Gazette* of January, 1906, Dr. Robertson's presidential address, delivered at the annual meeting of the Queensland Branch of the British Medical Association, is published. In it he gives his experience of thirteen cases of angina pectoris, all treated by the same intranasal procedure as asthma. He says: "In no case has there been no result, and improvement has generally been more rapid than in the other neuroses." In some the beneficial results were very striking, amounting to practical cure. Dr. Francis also has had several most successful cases, which I believe he intends shortly to publish.

It should be added that in angina pectoris, as in asthma, iodide of potassium, when given in sufficiently large doses, affords in many cases marked relief from the tendency to the recurring paroxysm. The use of the drug at present remains, so far as I know, empirical.

DIAGNOSIS AND TREATMENT OF THE ACUTE INFECTIONS OF THE GALL-BLADDER.*

By LUCIUS W. HOTCHKISS, M.D.,

NEW YORK.

ATTENDING SURGEON BELLEVUE HOSPITAL; JUNIOR SURGEON ROOSEVELT HOSPITAL; CLINICAL LECTURER AND INSTRUCTOR IN SURGERY, COLUMBIA UNIVERSITY.

THE great frequency of gallstone disease makes the consideration of one of its most common complications a subject of interest alike to the general practitioner and the surgeon. Acute cholecystitis is so common a complication of cholelithiasis that a knowledge of its symptoms and treatment becomes hardly less important than that of appendicitis, albeit its progress and results may seem less rapid and destructive.

It is an undoubted fact, as Moynihan points out, that the commonest manifestations of the presence of gallstones are never referred by the patient, and too rarely by his medical adviser, to the gall-bladder and its ducts. It requires even yet the unmistakable evidence of jaundice to associate the suffering with gallstones, even to the minds of some medical men. Yet, as we know, jaundice is an inconstant and infrequent symptom.

In the second place, quoting again from the same author, it must not be assumed that though no momentous symptoms of gallstone irritation are present, all is yet well with the patient. In cases in which the most obvious and undoubted symptoms have been present for only a few weeks, there will often be found at operation abundant evidence of chronic inflammation, or even malignant disease, that is but an expression of long-persisting local irritation. It is not, therefore, strictly accurate to say that in the majority of cases gallstones cause no symptoms.

Time will not permit, in a paper of this sort, the discussion of the whole subject of cholelithiasis and its complications, so the writer has selected a group of the different varieties of acute infections of the gall-bladder, which ought to be susceptible of diagnosis in most cases by the attending physician, and which at the same time under prompt and effective surgical treatment yield the greatest number of favorable results, both as regards life and freedom from further trouble. The growing tendency to place within the category of surgical affections many of the diseases of the gall-bladder, which, until very recent years, were entirely within the domain of internal medicine, must be regarded as a mark of growing confidence in the effectiveness of modern surgery in this field of work.

While the pathology of gallstone disease has been rewritten, largely as a result of the observations of the surgeon, of the actual conditions found at the operating table, the diagnosis of these various conditions, unfortunately, has not quite kept pace with the developments in technique. It is of great importance, therefore, to study and compare most carefully the symptoms observed, with the actual surgical findings in each case, so that the physician and surgeon may each understand the other's point of view, and some common point of agreement be reached as to what cases had better be operated upon, and in which cases delay may be counseled with moderate safety. The symptoms of gallstones in the gall-bladder and cystic duct, to which your attention is directed, are those of acute cholecystitis, and they vary, of course, in accordance with the virulence and intensity of the infection. That is to say, where there is no infection there is no cholecystitis, and where there is no cholecystitis of appreciable degree, there are no definite symptoms, except perhaps the colics.

Acute cholecystitis in its various forms is the most common variety of inflammation caused by gallstones.

When a stone becomes blocked at the entrance of the cystic duct, infection, as a rule, speedily follows; effusion takes places and inflammation of the walls of the gall-bladder follows. An acute inflammation, therefore, may be the forerunner of either a hydrops or an empyema.

The inflammation may start at either the fundus

*Read at a meeting of the Erie County Medical Society, Erie, Pa., April 3, 1906.

or any other portion of the walls of the gall-bladder. The swelling rapidly spreads until the whole of the mucosa is involved and the opening of the cystic duct becomes blocked. Thus it happens in acute cholecystitis that the occlusion of the cystic duct may be either the primary cause or the secondary result of the inflammation.

The symptoms, then, of an acute attack of cholecystitis are similar to those of an ordinary attack of biliary colic, except that the gall-bladder is enlarged, tender, and frequently palpable. Jaundice is never present in these cases unless the inflammation extends down the mucosa of the cystic and involves that of the common duct. Such extension is extremely rare. The swollen gall-bladder is sometimes the seat of pain, which may radiate to the back, the chest, or the abdomen, and the affected side may feel stiff and sore for days.

The varieties of acute inflammation of the gall-bladder are (1) the catarrhal, (2) the suppurative, and (3) the phlegmonous or gangrenous. Any of these forms may arise independently of gallstones, but in most cases it is the damage done by a calculus that opens the path to infection either from the contiguous gut or through the blood stream.

The symptoms of acute cholecystitis are not unlike those of appendicitis, and any of us may perhaps be pardoned for occasionally mistaking the one for the other. The writer is free to confess his fault in this direction.

Pain, the first symptom, is sudden in its onset, increasing rapidly, and may be paroxysmal or continuous. It is felt mostly over the liver, especially along its lower border, but it may radiate widely and mimic closely, the pain of acute appendicitis, or subacute perforation of the stomach or duodenum.

Other symptoms of infection soon occur, and nausea, often vomiting, prostration more or less marked, and tenderness over the region of the gall-bladder opposite the right ninth or tenth costal cartilages become marked features in the case. If the infection extends through the walls and involves the overlying peritoneum of the gall-bladder and adjacent viscera to any considerable extent, the symptoms become more severe, and may closely resemble those of an acute intestinal obstruction. The temperature is generally elevated to 100° or more, and the pulse becomes feebler and more rapid.

The organism found in cultures taken from cases of acute cholecystitis is generally *B. coli communis,* though in the suppurative forms streptococci and staphylococci are frequently present. The typhoid bacillus and the pneumococcus may also be found. Indeed, the relation of typhoidal infection to many cases of acute cholecystitis, with or without stones, is undoubtedly causal and always striking and suggestive. In only one case has the writer seen an acute cholecystitis develop in the early days of typhoid fever, although it not uncommonly follows the disease, apparently as a direct sequence. So long as the inflammation is limited to the mucosa, the symptoms are apt to be mild, and the life of the patient is not endangered, although an intense infection may follow a mild one, as happened in one of my own cases hereafter reported. One attack of cholecystitis predisposes to another from the fact that the stone is not usually passed out of the gall-bladder, but drops back again ready to start up another more or less severe attack after a variable period of latency.

This period of "latency" so called varies much in different cases; it is sometimes short, sometimes very long, and upon the fact that some cases of troublesome stones reach a period of "latency" is based the claims of certain cures by internal medication. Indeed, if one could predict infallibly that the period of latency in a given case would be very long, or practically under the control of internal remedies, this of course would be a rational ground for the physician to deny the necessity or desirability of operation. This, of course, being impossible, in cases especially where the periods of latency are short, and the suffering in the attacks is considerable, other things being equal, the choice lies between operation and its known results and the cultivation of the opium habit and a condition of chronic invalidism. Although Naunyn has claimed that a *restitutio ad integrum* is possible after a single attack of undoubted cholecystitis, it is not probable, to say the least, from a knowledge of the pathology, and cannot be counted upon. The stone, which remains behind in the bladder after most attacks, lies ready to renew the attack again and again, and the barriers of defence gradually diminish in the presence of ulcerations, strictures, and other structural changes in the walls of the gall-bladder and in the adherent surrounding viscera. In many cases, even when the symptoms are slight, the inflammation penetrates the peritoneal coat, and plastic lymph, replaced later by more or less dense adhesions to adjacent viscera, may render more difficult the best-planned operation for relief. These adhesions may persist, even if the stone or stones do pass into the intestine, and give rise to symptoms identical with the original trouble, all of which facts argue for early operation.

As a rule, the tenderness and rigidity of muscle are limited to an area immediately below the free border of the right ribs, just below the free edge of the liver. When a tender mass is palpable, the diagnosis is easy, but the gall-bladder is frequently tucked under the projecting Riedel's lobe, and is not palpable. In these cases the tenderness and muscular rigidity of the upper segment of the right rectus muscle, together with the tenderness elicited by pressing the hand under the free border of the right ribs and getting the patient to take a deep inspiration, which is immediately and strikingly interrupted when the inflamed gall-bladder is crowded down, will make the condition clear.

The most serious form of acute cholecystitis is the phlegmonous variety, wherein all the signs and symptoms are much more intense and threatening, and the results almost inevitably fatal in short order, if immediate surgical operation is not performed. The clinical picture in this variety may perhaps best be illustrated by one of my own cases of acute phlegmonous cholecystitis of recent date.

F. E., male, 53 years old, admitted to Roosevelt Hospital, January 22, 1906.

Family history, negative. He had typhoid fever at 14 years of age.

One year ago he had an attack of pain in the right side radiating to the shoulder, with fever and slight chill; he was slightly jaundiced, and was in bed 14 days. He was seen by Dr. Blake, who advised operation on the gall-bladder, which the patient declined. Since this attack the man has suffered considerably from indigestion, "biliousness," and headache. Five days before admission he was seized with a "deep, unbearable" pain, in the epigastrium and gall-bladder region, which radiated slightly into the shoulder. This attack followed an indiscretion in eating. His physician reports him to have been without fever until the day before admission, when he was seized with severe pain and went to bed

again. On the morning of the day of admission he suddenly became very ill, alarmingly so; his temperature shot up to 106°, his pulse went to pieces, and he became slightly delirious. He was seen in consultation with Dr. Stern, and found in bed with a tender spot over the gall-bladder, but no tumor was felt. He was advised of the seriousness of his condition and immediate operation urged, which he declined. In the late afternoon, his condition becoming worse, he was sent to Roosevelt Hospital.

He had had no vomiting, but very slight jaundice, and clay-colored stools were noticed on day of admission.

On admission temperature was 107°, falling before operation to 104.5°. He looked very sick, and his pulse was rapid and of poor quality.

There was no abdominal distention, no tumor, but very marked tenderness over gall-bladder region, and on lateral compression of the ribs. There was rigidity of the upper segment of the right rectus. A diagnosis was made of acute cholecystitis, and the patient was prepared for operation. Leucocyte count, 4,500 to 5,000. Differential showed polynuclears 87 per cent., lymphocytes 11.5 per cent., large mononuclears 5 per cent., transitional 1 per cent. Red blood corpuscles, 4,000,000. Examination for malaria was negative. The urine was dark reddish in color, sp. gr. 1022; light cloud of albumin, many hyaline and a few waxy and granular casts. On the third day after operation, when the temperature rose to 103°, the leucocyte count was 15,000; polynuclears, 87 per cent.; others, same as before; red blood corpuscles normal in number.

Operation—incision through the upper right rectus. The gall-bladder was large, but concealed under the right lobe of the liver, distended, and soft pus was obtained on aspiration. The wall was succulent and easily torn, recent fibrin on surface. It was detached from the under surface of the liver without much hemorrhage. The cystic duct and artery were clamped and tied with catgut, and the gall-bladder was excised. A rubber tube, wrapped in gauze and covered with rubber tissue, was passed to the stump.

On opening the bladder no stones were found, but the mucous membrane was deeply congested, soft, and ulcerated in spots, and the walls in places seemed almost gangrenous. The pathologist, Dr. Hodenpyl, reports intense exudative inflammation, involving the entire wall of the gall-bladder, which is considerably thickened, and he adds that the patient is entitled to a secondary liver abscess. Saline infusion, 1,000 c.c., was given during the operation. Patient returned to bed in fair condition; some pain; morphine and saline irrigations later.

Next morning the temperature fell to normal and the patient felt comfortable, though very weak. On the third day the temperature rose to 103°, but soon became normal again, and this fall was accompanied and followed by a discharge of bile from the wound, which continued only for a few days and in much diminished amount. The patient was very drowsy. Saline irrigations through a rectal tube were given.

The first satisfactory movement was obtained on January 28. Two days later the drain was removed and the sutures taken out. The wound was in a satisfactory condition. A small gauze drain was inserted and straps applied.

The patient was discharged on February 11. Differential count showed polymorphonuclears, 87 per cent.; lymphocytes, 11 per cent. Convalescence was marked at first by the sleepy condition of the patient and occasional headaches and difficulty of securing a satisfactory movement of the bowels. At time of discharge there was small sinus, with practically no discharge. The patient was able to get about the halls well and without much fatigue. The condition of the urine cleared up considerably, and at the time of the patient's discharge showed a sp. gr. 1018, faint trace of albumin, a few hyaline casts, and a few leucocytes.

The clinical features of this case are very striking, and the close relation between the symptoms and the pathology, together with the prompt relief afforded by operation, are very impressive. Cases of this sort should not be overlooked very frequently, and when the diagnosis is made only prompt operation can save them.

The course of a case of acute catarrhal cholecystitis varies within moderately wide limits, according to the degree and extent of the infection and the number and character of the previous attacks. As a rule most of the cases tend to resolve, although a certain proportion of them, beginning with mild symptoms, become suddenly hyperacute and demand surgical interference. The symptoms, pain, tenderness, and tumor, after a longer or shorter time, may gradually or rather suddenly disappear, and the attack ends, only to be repeated at a longer or shorter interval. One waits with greater confidence for the resolution of an attack of acute inflammation of the gall-bladder than in a similar attack of acute appendicitis, for even in a moderately sharp attack of acute cholecystitis the symptoms at the end of two or three days are as a rule the cause of less anxiety than at a similar period of acute appendicitis. When, however, the symptoms are becoming more severe, it is better to operate promptly than to wait, for operations on the gall-bladder seem to be equally well borne in the period of acute inflammation or in the interval between attacks. This at least has been the experience of the writer.

The indications for operative treatment in acute cholecystitis are evident to all who have seen upon the operating table the serious conditions which result from delayed surgery. Every practitioner should renew his knowledge of the pathology of gallstone disease by a careful study of actual conditions observed on the operating table, and direct his patients accordingly. It is unfair to the patient and to the surgeon for the internist to base his advice as to operation upon the results in delayed and complicated cases and those in which operation is undertaken as a forlorn hope. In justice to American surgery he must base his conclusions upon the best results of the best men and put the question fairly to the patient who comes for relief. There will always be many cases which will never entertain any question of operation except as a last resort, and there are many others with mild and infrequently recurring attacks of cholecystitis to whom the joys of Carlsbad appeal with greater fascination than the cold logic of surgery. Then there are other cases in which, by reason of age, in connection with some grave lesion of heart or other viscera, no operation would be undertaken except in some dire emergency. Ruling all these out of consideration, there remains a large number of cases of recurring acute cholecystitis, mostly young or in vigorous middle life, whose existence is often made miserable by recurrent and severe attacks of pain which incapacitate them for longer or shorter periods. Can the medical man safely recommend surgery in these cases? A survey of the literature of the subject will abundantly justify an affirmative answer. The statistics of recent

years show a mortality so low in cholecystostomy and primary cholecystectomy, that the internist may offer his patient a surgical operation for the relief of his suffering which is prompt, efficient, and safe in any proper case, and offers the only radical and curative measure of which we have any knowledge.

The promise of a brilliant future in gallstone surgery lies not in the elaboration of technique so much as in the prompt diagnosis and early resort to the simpler operations upon the gall-bladder, before serious infection, adhesions, duct invasions, and blood changes have made any undertaking more severe, more hazardous, and less effectual. As greater certainty in diagnosis is reached, there will be less call for the difficult and more dangerous operations upon the common duct, a smaller number of cases with acute and chronic pancreatitis, and the operation of cholecystenterostomy will become very much rarer than it is now. One has only to glance at any large table of operations for gallstone disease to appreciate the truth of these statements. In the 1,000 cases reported by the Mayos a year ago, 673 were operated upon by cholecystostomy, with a mortality of only 2.4 per cent. This group included most of the acute infections of the gall-bladder, and this was the operation of choice where cholangeitis was or had been present and where drainage of bile was an important factor. There were in this same group also 186 cholecystectomies done, with a mortality of 4.3 per cent. There were 137 operations upon cases of common-duct stone, with a mortality of 11 per cent. The marked increase in mortality in the cases of late infections and common-duct obstruction is very striking and suggestive.

The scope of this paper limits the discussion to the treatment of cases of acute infections of the gall-bladder. What should be the attitude of the physician toward the question of operation in these cases? Can he safely recommend it, or is it safer to wait and let the patient drift along? Cases seen in the first attack (seldom seen by the surgeon anyway), in which the symptoms are slight, rapidly subsiding, and there is no peritonitis, may properly be considered fit cases for observation for careful diagnosis. In a small proportion of these cases (about 10 per cent. according to Elsberg) there is only one stone, or only very small stones and mucus, which pass out into the intestine and the cholecystitis disappears. In about 70 per cent., it is estimated, the stone does not pass, but remains in the cystic duct or drops back into the gall-bladder, where it remains latent for a while, the swelling of the gall-bladder disappearing. Cases seen in subsequent mild attacks present a nice problem, in that they are often ideal cases for primary cholecystectomy, which one naturally hesitates to urge in the absence of an absolutely certain diagnosis. Such a case has recently come under my charge in the person of the wife of a physician, in which the question was a difficult one, but, aided in the solution I must say by the very sensible attitude of both patient and her husband. In this case symptoms had been present less than a year, but were acute, and the attacks were becoming more frequent. I removed her gall-bladder a few weeks ago and found an acute cholecystitis and several moderate-sized rough stones, the cystic duct being nearly occluded by one of them. In this, as in similar cases, I removed the gall-bladder, as it was practically cut off from the bile circulation and there was no cholangitis. The operation is often a very easy one, especially when one uses a sandbag under the back to push forward the gall-bladder and ducts, and it takes no more time than a cholecystostomy in which the gall-bladder is stitched to the parietal peritoneum and drained. Wherever the necessity of drainage is present, and it often is imperative, an operation which provides most easily and safely for it is the best one. Thus many surgeons employ cholecystostomy as fulfilling all the indications in the simplest manner, while others prefer to remove the gall-bladder, when this can be done easily and without sacrificing the interests of the patient, and drain when indicated from the cystic duct, which is readily accomplished. Park, Riedel, Winiwarter, Lilienthal, and many others are warm advocates of primary cholecystectomy as the ideal operation when possible, and an increasing experience leads the writer to believe that the indications for this operation are constantly broadening.

A third set of cases exists which for a few days give evidence of only mild local infection, but suddenly develop signs of local peritonitis, with heightened fever, rapid pulse, and signs of general sepsis. These cases all require early operation, a prompt cholecystectomy or cholecystostomy, with drainage of the gall-bladder. Under this treatment many recover who would surely go on to death from sepsis or perforation and general peritonitis. As is well known, the common-duct cases, so called, are the most dangerous because most often overlooked or neglected until, in a condition of exhaustion and cholemia, they come to operation. It is surprising that so many of these patients recover. Modern surgery has made even this possible, but it should be always remembered that a chronic jaundice and cholemia will often defeat the most perfectly planned and executed operation, and that the hemorrhagic oozing so common in these cases may go on to a fatal termination, in spite of any treatment thus far devised. It should be our duty, then, to advise early operation in infections of the gall-bladder before perfectly preventable complications exist, and we should expect as satisfactory results as in cases of appendicitis, which are submitted to early operation and with no greater mortality.

ILLUSTRATIVE CASES OF PROSTATIC CARCINOMA.

By J. BENTLEY SQUIER, M.D.,

NEW YORK.

A critical study of recent literature of malignant neoplasms of the prostate produces the impression that carcinoma of the prostate, along with carcinoma in other situations of the body, is notably upon the increase. In the past it has been considered an extremely rare occurrence, although recognized to be the usual variety of malignant growth of the gland. The fallacy of this doubtless lies in the poorer methods of diagnosis of a decade ago and the comparative infrequency of surgical attack upon the organ prior to that period. Thus many cases of prostatic carcinoma have probably been diagnosticated under the generic term of enlarged prostate which, if their true structural nature had been investigated, would have proved to have been malignant. Such an observer as Albarran has demonstrated carcinomatous changes in from 10 to 14 per cent. of cases of prostatic hypertrophy. The impetus which operators during the past few years have given to prostatic surgery in their attempts to alleviate the suffering due to urinary obstruction, coupled with more accurate microscopical diagnosis, have probably been the potent factors in the production of the

seeming increase of the disease. At all events, the prostate is one of the rarest localities for carcinoma to become manifest. In a thousand cases of carcinoma in various situations Weber found only thirteen involving the urinary organs. Even in the reported cases the diagnosis, in many instances, is still doubtful because of the possibility of confusing hyperplastic growths with true carcinoma.

Prostatic cancer presents itself at the two extremes of life, namely in early childhood or in advanced years. About four-fifths of all malignant growths of the prostate are carcinomatous. There is a diversity of opinion as to the relative frequency of the growth being primary or secondary in the prostate. Not infrequently tumors are described as primary, when the origin is really from the epithelium of the bladder, the growth invading the gland secondarily. We believe it is more often primary than is ordinarily supposed, and develops either in the mucosa of the prostatic urethra, diffusely through the entire gland, or may form a discrete nodule in one portion of it. The process may be of the medullary type, or show the structure of adenocarcinoma. In regard to extension to other organs, Guyon claims that carcinoma, which is primary in prostatic origin, is more liable to invade the pelvic lymphatic system than to extend directly to the bladder. If the growth invades the bladder it is along the ejaculatory ducts into the posterior wall. Extension into the pelvic tissues and viscera, with final invasion of the bones of the pelvis, is met with only in late cases. When once the bone is involved the tumor may assume a diffuse form and involve a considerable portion of the pelvis, the vertebral column, and the long bones of the lower extremities. Exceptionally, the entire skeleton may be involved even when the primary growth is relatively small. Secondary carcinoma is usually due to an extension of a renal, vesical, or genital lesion. The cases which I have selected to report in this paper, although very characteristic, embody certain features of special interest, which, I think, justifies a more or less detailed presentation of their histories.

Case I.—This patient, who was eighty years of age, had been an invalid for many years, suffering from a large, right-sided, irreducible, inguinal hernia. Although incapacitated on account of the size of the hernia, there had never been any obstruction of the intestinal function. He denied any venereal or previous urinary history. The condition presented itself as follows: He awoke one morning, and to his surprise found his bed-linen and night clothes saturated with blood. He found the source of the hemorrhage to be from the meatus of the penis. He stated that at no time had he ever observed blood in the urine or exuding from the meatus. The interval of urination had been every four hours during the day and about the same at night. The urinary flow had always been free and absolutely painless. The only symptom was the hemorrhage. Spontaneous urination was impossible. He was a large, plethoric man, and unusually well preserved for his years. Physical examination was negative, except for a greatly distended bladder, the fundus of which reached almost to the umbilicus. By rectum a hard, diffusely enlarged prostate could be felt. A soft catheter drew 10 ounces of blood and urine. Local measures failing to check the constant urethral oozing, suprapubic cystotomy was decided upon. This was performed six hours after the initial bleeding occurred. The bladder was found distended with blood clot, which, being evacuated, a hard, nodular mass was found involving the whole of the prostate. The hemorrhage emanated from an ulceration on the left side of the tumor near bladder base. The patient's condition, on account of the large amount of blood already lost, did not warrant any extensive operation for the tumor's removal, so the bladder was merely packed and drained, no attempt being made to enucleate the tumor. He required infusion while on the table, and left the operating room in grave condition. He recovered from the operation in much better condition, however, than could be expected. During the first day he drained thirty ounces of urine through the tube in addition to the amount which leaked into the dressing. His highest temperature was only 100.4°F., with a pulse of 80 and respiration of 22. He held his own for two days, when uncontrollable vomiting of bile-tinged fluid set in, and he died suddenly four days following operation, apparently from exhaustion. There was no hemorrhage after the bladder had been opened and packed.

The autopsy findings, which were most unlooked for, in view of the fact that the patient had presented no symptoms referable to some of the lesions found, were as follows: Heart, normal; lungs, a few adhesions at base behind; liver increased in size; Spigelian lobe showed a thick layer of pus and fibrin, forming superior boundary of an abscess cavity; gall-bladder distended, contained numerous gall-stones; its surface covered with inflammatory exudate, with marked thickening about common, and cystic ducts forming part of the abscess wall. Duodenum: An inch and a half from pylorus on posterior surface were two ulcers, with clean-cut edges, communicating with the abscess. The uncovered portion of the duodenum was covered with plastic exudate, and formed last boundary of the abscess. The abscess contained two ounces of pus. The prostate was large, hard, and from the left lobe sprung a papilomatous ulcerated growth. Pathological examination showed the tumor to be carcinomatous, with deposits throughout the whole prostate.

Löwenheim has reported a case of sarcoma of the bladder with metastatic sarcomatous gastric ulcers, but in the case just cited the writer is led to believe the dual condition a coincidence. The duodenal ulcers presented no anatomical or microscopical evidence of being malignant in character.

Sudden hemorrhage from the bladder, especially if unattended by pain in a man over fifty years of age, who gives no history of previous bladder trouble, is most indicative of prostatic cancer. In purely vesical growths pain is more apt to be an early accompaniment of the hematuria, obviously depending somewhat upon the location of the neoplasm. In Young's series of forty cases, however, he states hematuria present in only eight cases, in four of which the bladder was involved as well.

Case II.—This, like the preceding, is another one in which sudden hemorrhage from the bladder first directed the attention of the patient to his malady. He was fifty-four years of age, and in his own estimation never enjoying better health. While on a railway journey he felt a desire to urinate. This he tried to do, but was unable to for ten minutes, when, with a gush, he voided a large quantity of blood clots and bloody urine. This was followed by frequent urination of bloody urine for twelve hours and a slow cessation of the hemorrhage. The only previous history of any urinary disturbance consisted in two attacks of frequent urination and burning in the perineum, one following a long horseback ride and exposure to cold ten years before, and the second, five years later, after a tedious donkey ride in Egypt.

After the initial hemorrhage had cleared up, the patient would void bloody urine only at intervals, usually worse at night. Not having any pain, he did not become alarmed about himself until the symptom had existed for two months, when he came under our observation. Cystoscopy, which was performed with difficulty on account of the size of the prostate and bleeding, demonstrated a bleeding tumor projecting from the right lobe of the prostate. Suprapubic opening of the bladder and removal of the tumor was decided upon. This was carried out some days later. A sessile tumor was found springing from the prostate, near the base of the bladder, with nipple-like projections into the trigone. The prostate, tumor, and its projection were removed by extensive blunt dissection, and the base of the bladder was cauterized by the actual cautery.

Subsequently to the operation the patient did well for twenty-four hours, when he developed intestinal paresis and died from peritonitis at end of the third day. It was impossible to obtain a general autopsy, but the pelvic viscera were examined after death through the suprapubic incision, and no macroscopical extension of the growth into them noted. Sections of the prostate, tumor, and projections of it into the trigone proved to be carcinoma.

One of the most distressing features of prostatic neoplasm is that the growth has advanced to an almost inoperable extent before it becomes manifest to the patient by subjective symptoms.

Case III.—This case furnishes a typical illustration of what has just been mentioned. When first seen the patient stated that for several months past he had been obliged to urinate frequently day and night, had paid no particular attention to it, and it was only at the solicitation of his wife that he consulted a physician. When examined he was urinating every two hours, with smarting pain in the glans and at times a little blood in the urine. Per rectum a moderately enlarged prostate was felt, with no tenderness in it excepting in the posterior lobe, where he complained on the slightest pressure. Examination of urethra or bladder was impossible on account of the exquisite pain produced when an instrument touched the prostatic urethra. Expectant measures were instituted, and after a few days, his general condition becoming worse and the patient demoralized about himself, he was given an anesthetic, with permission to open the bladder if, after examination, it was deemed advisable. A searcher introduced into bladder, requiring marked depression of the handle to do so, was obstructed in rotation by a large mass in the right lobe of the prostate. It was decided to open the bladder and ascertain the pathological condition present. A large mass of carcinomatous tissue was found occupying the prostate and base of the bladder, and surrounding the internal meatus. It was inoperable. The bladder was drained by Gibson's method.

Sections removed for microscopic examination proved to be carcinoma. The patient died at the end of two days from peritonitis, probably due to colon bacillus infection. Whether this tumor was primary or secondary in the prostate is impossible to know.

The rapidity of the growth of prostatic cancer is dependent, as elsewhere, upon its structural composition.

Case IV.—Scirrhous carcinoma of the prostate. The patient was sixty-two years of age. For two years before coming under observation he had gradually increasing feebleness of stream, hesitancy, frequency, and nocturnal urination. No pain until these symptoms had existed eighteen months, when intermittent hematuria appeared. The relation of the symptoms was not constant, the pain, blood, or frequency occurring independently of each other. The pain was referred to the glans penis and perineum. By rectum the finger palpated a large, broad, elongated prostate, the middle lobe of which was very hard as compared with the rest. Toward the apices of the lobes were hard, irregular nodules. Urethral length, 8¼ inches; 10 ounces of residual urine. The bladder was opened by suprapubic incision. An irregular, friable tumor was found involving the prostate and surrounding the internal orifice of the urethra and extending into the prostatic urethra. The whole of the prostate was removed, together with the neoplasm. The morphological appearances of the tumor showed it to be largely composed of connective tissue, with diffuse inflammatory infiltration with pus cells. A number of the fragments contained strands and masses of epithelial cells not arranged in regular groups. The patient did well, and for some months after operation was as comfortable as if he had had merely a prostatectomy performed for simple hyperplasia; but slowly the lesion reasserted itself, the extension being into the urethra. *X*-ray treatment was used with no benefit, and ten months after operation, when he was lost sight of, the only comfort he could get was by frequent recourse to opiates.

Case V.—This is a case in which the writer removed a scirrhous carcinoma of the prostate, the patient living a year. Permanent suprapubic drainage was instituted at time of operation, and the patient enjoyed a measure of comfort until recurrence of the growth filled the pelvis and obstructed the rectum. In this case also *x*-ray treatment seemed to have no effect upon retarding the growth.

In reviewing our experience and that of others, the futility of our endeavors to do more than palliate the patient's sufferings by operation is only too apparent.

The whole question resolves itself into one of early diagnosis and operation if we are to accomplish any lasting results. If the steadily increasing number of reported cases prove carcinoma to be suspicious in a tenth of cases of prostatic enlargement, we must be more acutely on the lookout for it. As we have come to regard the smallest tumor in the breast as a possible focus of malignant trouble, and hesitate to pass judgment upon it until microscopical sectional diagnosis has aided us, so ought we to hesitate in pronouncing enlargement of the prostate to be simple hyperplasia until it has been so proven by the pathologist. The early recognition of carcinoma in any locality is imperative, and nowhere more so than in the prostate. Unhappily, this is a very difficult problem. The cystoscope may reveal merely an increase in size of the gland, while beneath its firm capsule an insidious destroyer of life is forming, only to burst forth into too certain cognizance when we are impotent to remove it. It is a sad commentary that practically our operative endeavors are only directed towards rendering the remainder of the patient's life more livable. The majority of patients, if the disease is at all advanced, live longer if palliative measures are employed than by extensive radical operation. Permanent suprapubic drainage has, in our hands, given the greatest comfort to the patient.

Watson offers bilateral lumbar nephrostomy and the establishment of permanent renal fistulæ, with or without removal of the tumor, as the case may allow, for relief of vesical malignant disease. This might include similar disease in the prostate, as the conditions are so intimately allied. We fail to see

the improvement in this oversuprapubic drainage, except in such cases as permit total removal of the tumor, or unless it can be proven that the diversion of the current of urine inhibits the rapidity of the extension of the growth.

Young's four cases of removal of the entire prostate, seminal vesicles, vasa deferentia, and major portion of the vesical trigone for prostatic cancer, are brilliant results, and illustrate how well a small amount of bladder left behind will adjust itself to perform the function of the intact organ. As we have learned in dealing with carcinoma elsewhere, radical cure can be only hoped for by early operation and wide removal. The symptoms offered by the patients are not pathognomonic, and the results of our physical examination often leave us in doubt as to the true nature of the disease. It seems, therefore, that the only line of surgical advance points clearly to the fact that in operating upon any hypertrophic condition of the prostate, we should make use of the additional data derived from microscopical examinations of frozen sections at time of operation in order to determine the extent of our operative procedure.

KOPLIK SPOTS; THEIR RELATION AND INTEREST TO LARYNGOLOGISTS.

By H. GLOVER LANGWORTHY, M.D.,

DUBUQUE, IOWA.

EX-HOUSE PHYSICIAN INFECTIOUS WARDS BOSTON CITY HOSPITAL. EX-AURAL HOUSE SURGEON MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY. OPHTHALMIC HOUSE SURGEON MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY.

Although the study of the anthemata of measles belongs mainly to the province of the general practitioner, the attention of throat specialists is called especially to the early prodromal eruption in the mouth, the diagnosis of which goes far toward solving the problem of controlling the spread of epidemics. Every now and then a case is seen in either the hospital or clinic exhibiting the tiny pearly white Koplik eruption on the mucous membrane of the buccal surfaces. Occasionally, also, the specialist is called to verify the diagnosis before the eruption, already begun on the face and chest, and has progressed sufficiently as to be self-evident.

Considerable satisfaction is derived from an opportunity of isolating a child exhibiting the pathognomonic sign of measles, informing the parents as to the nature of the contagion and two or three days later, having our foresight rewarded by the appearance of the characteristic maculopapular eruption on the skin.

If the inner surfaces of the mucous membranes of the cheeks are carefully examined in the slightest indisposition of children, we can in most instances diagnose the disease at least thirty-six hours before the later cutaneous eruption.

For some reason I have noticed that Koplik spots appear the earliest on the mucous membrane, near the angle of the mouth and in areas covered by the gums. When there has been a history of exposure, plenty of warning is usually given by a persistent cough—in some instances a week or more before any other symptom.

A good, clear, strong light is essential; reflected light cannot always be relied upon. What we are looking for is the tiny pearly white spot on a red background of mucous membrane. The actual deep injection of the hard and soft palate and reddening of the mucous membranes in general, are the latest of the prodromal signs and not especially distinctive.

There is probably no such hybrid as so-called German measles. This type is merely a slightly atypical picture, likely to be met with in any disease. Certainly the ordinary type of measles can be contracted from this abortive type. Dr. Henry Koplik of New York maintains that the exanthema, the eruption in the mouth which bears his name, may be present fully five days before the exanthema, the eruption of the skin, and this without any manifestation whatsoever to signalize the onset of the disease. From the fact that in hospital wards the spread of the contagion is checked among the children if the cases are isolated before the skin eruption we infer that the prodromal rash is contagious to but a very moderate extent. To Dr. John H. McCollom of Boston (chief of infectious wards, Boston City Hospital) we are also indebted for many observations along these lines, gathered from a peculiarly rich experience of many years. His remarks on smallpox and diphtheria do not by any means form his chief contributions to literature.

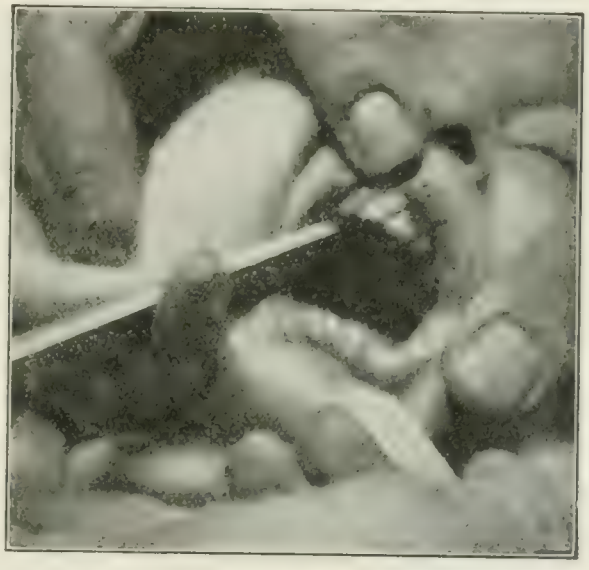

Fig. 1.—Koplik's prodromal eruption on the lips and gums in a child 5 years old. Taken ten hours before the exanthemata was at all characteristic. The papular infection of the face is the result of a purulent discharge from the right eye.

The following classical description by Koplik conveys as clear a word picture of the prodromal sign as can be given: "On looking at the mucous membrane lining the cheeks (buccal) in strong sunlight a very characteristic eruption of irregular stellate or round rose-colored spots is seen. In the center of each spot there is a bluish-white speck. This appearance of a bluish-white speck on a rose-colored background is pathognomonic of the onset of measles. The speck is sometimes so minute that strong light is necessary to render it visible. The number of specks at the outset may be less than half a dozen. In a short time they become more numerous and the rose-colored spots become confluent, so that there are diffusely red patches of buccal mucous membrane studded with bluish-white specks. They are seen on the inner surface of the lips and gums."*

This eruption practically disappears when the exanthema on the body becomes well developed. Sometimes the minute bluish-white specks coal-

*Koplik, H.: Diseases of Infancy and Childhood, p. 262, Second Edition.

esce and form larger white spots on the lips, as may be seen in Fig. 1. The appearance of the eruption on the mucous membrane of the cheeks when at its best is not unlike a countless number of checker-boards grouped together. Neither photograph brings out the white specks on the gums or cheeks very well. A raw area is left when the Koplik spot disappears. The spots are never seen on the hard or soft palate or pharynx.

Aphthous stomatitis is probably the principal condition which might be mistaken for measle spots. It is usually readily distinguished by the fact that the small ulcerated areas are situated on normal mucous membrane and are more or less yellowish-white in color and always discrete. The active eruption of measles is in itself a form of stomatitis.

Now and then irregular teeth and decaying food particles will produce irregular, very small white blemishes on the mucous membrane of the cheeks, but their location and situation on perfectly normal membrane under normal nonvarying conditions, will preclude a mistaken diagnosis. The early Koplik spots can be so mutilated by

Fig. II.—Koplik's eruption on the mucous membrane of the left cheek of the case illustrated in Fig. I.

the mechanical introduction of the wooden tongue depressor as almost to prevent temporarily an interpretation of their real nature.

The patient who furnished the accompanying pictures was a child five years of age, an inmate of the Massachusetts Charitable Eye and Ear Infirmary. He had been directly exposed to the contagium. A slight, infrequent, but gradually increasing cough was noticed eight days, the first Koplik spots three and one-half days, symptoms or coryza two days, and moderate temperature one day, before any eruption on the skin. The cough was the rather hard, dry, hoarse laryngeal cough almost peculiar to the condition.

As measles is perhaps the commonest of the infectious diseases of childhood and very few individuals arrive at adult age without having had an attack, the necessity of an early diagnosis for quarantine purposes cannot be emphasized too strongly. The Koplik eruption practically removes the greatest element of uncertainty in the early diagnosis, hence there can be little excuse for the continued and wide extension of the disease.

The discovery of the contagium still continues to withstand our best endeavors. Whether we should seek the specific poison in the secretions of the upper respiratory tract, in the actual eruption on the skin, or in the blood is still a matter of doubt. Certainly the contagion is so virulent that when once introduced into a hospital ward the spread of the disease is rarely checked until either all of the unprotected children suffer or the cases are isolated in time to prevent further mischief. One attack, fortunately, usually, protects against a second. The incubation period may be as short as seven days, or even as prolonged as three weeks.

The buccal complications and anginas of the infectious fevers surely merit considerable attention from both laryngologists and otologists, not only because of their frequency, but from a most practical standpoint. The angina of scarlet fever with a marked punctate eruption on the roof of the mouth and a strawberry tongue preceding a delayed rash, although rather rare, is given as an example. The ofttimes close similarity in appearance of a streptococcus patch to that of the true Klebs-Loeffler membrane on the tonsils needs but to be mentioned. Even syphilitic patches may be confounded with both.

My object in this paper is not to present any new theories or set of facts, but to call the attention of throat specialists more closely to an interesting condition which is occasionally observed.

THE MEDICAL MUSEUM.*

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

In every great metropolis peopled by men of superior intelligence the museum is a preeminently well-recognized institution. Thus, the treasures of art and science contained in the British Museum and the Louvre, in the Museum of Northern Antiquities of Copenhagen, in the vast collections of Vienna, Berlin, Venice, Florence, Rome, Naples, Seville, and New York constitute at once the chief ornaments of these respective cities and one of the most potent of their educational factors.

Among the various departments of science thus represented medicine has by no means been neglected. All great cities which by any courtesy can be called centers of medical learning have their medical museums. Washington, Philadelphia, Boston, not to speak of many of the cities of the old world, have famous collections, too well known to you to require mention. Strange to relate, our city, the greatest and most progressive of them all, has practically none. For many years it has been my hope that a collection worthy of the fame and wealth of New York might be established here. Thanks to the gentleman now in the presidential chair of the Academy of Medicine, the initiative in this direction has been taken, for he has recognized the possibilities of the situation, and by his own generous example and by the inspiration of his enthusiasm has opened the way for us to follow him in the accomplishment of this important work.

Should any question arise as to the value of the suggestion which he has made, it may easily be answered. A collection such as is proposed for the Academy of Medicine has the same reason for its existence as has that of the Historical Society, or even the written pages of history itself.

*Remarks on the presentation of a collection of laryngological instruments to the New York Academy of Medicine, October 4, 1906.

To be of use our collection should represent a truthful record of the past. Its scope, for the present at least, should be mainly historical. It should include old instruments, most especially such as have been original models of new inventions or as offer good examples of standard instruments of the time. Many good specimens of this kind are now available which in a few years will be surely lost.

Again, old prints and illustrations representing the men, the methods, and the customs of our profession in the past will have great and ever-increasing value. Without such a collection a great library would certainly be incomplete.

Finally, while the shelves of a practical working library should never be encumbered with obsolete trash, there are certain classes of ancient books which are of almost priceless value, for many reasons besides purely sentimental ones.

Many of the objects contained in such a collection would be unique. If lost they could not be replaced. Their permanent preservation, therefore, is a matter of vital necessity.

As to the functions of our museum, the specimens which it presents may be lively reminders of great men, and therefore worthy of contemplation. They are, moreover, mementoes of notable achievements, full of inspiration to the thoughtful mind. Again, marking the advance of knowledge, they are milestones in the onward progress of medical science.

Practically studied, the objects which the museum contains may be divided into two classes, namely, the good and the bad. It goes without saying that the suggestions to be gained from a good model will always be valuable, not only in the department for which the given article was intended, but, occasionally, in other departments possibly remote from it. No warning, on the other hand, is more eloquent than the spectacle of failure. The exhibition of the mistakes of others should certainly tend to prevent their repetition.

Finally, the settlement of questions of priority of invention is a matter of no small moment.

Aside from personal questions involved, the fact that an instrument of ancient invention has been lost to sight is often owing to the reason that it was not well adapted to the end which it was intended to serve. To revive such a model every few years under a new name is to confuse the mind of the profession and seriously to hamper progress. Instruments which to-day are bearing names contemporaneous with our own have been found among the ruins of Pompeii, and may readily be seen in the Museum of Naples.

For the furtherance of the various above-mentioned ends and of others which may reasonably occur to you, the collection proposed will be of great value. Other institutions having the proper facilities for so doing may establish museums of anatomy, biology, or pathology. With us such a course may not at present be open, either through favorable opportunity for collecting or through available exhibition space. There is plenty of room, however, for rare old books, for instruments of the right kind, and for interesting historical plates. If each one of us will do what he can as opportunity affords, that space may soon be most satisfactorily filled.

With myself this has been a long-cherished idea. In furtherance of it, I take pleasure in depositing the accompanying instruments, the beginning of a collection to which I hope from time to time to add, until it shall well represent the history of the early days of laryngology.

DRIED TETANUS ANTITOXIN AS A DRESSING FOR WOUNDS.

By J. J. KINYOUN, M.D., Ph.D.,

GLENOLDEN, PA.

Some observations on the use of tetanus antitoxin in a dried and powdered form as a dressing for wounds have been made which seem to justify its mention. It may be mentioned that Calmette[1] published a note giving his experiences with dried tetanus antitoxin in powdered form as an application to wounds infected with tetanus. I have confirmed his experiments, but have little or no success in preventing tetanus in the case of deep or penetrating wounds. In these, the preventive power of the powder is only slight, and in most cases its application is without effect.

It occurred to me that it would be good practice to apply this powdered antitoxin to the minor injuries, with a view of preventing tetanus, as many of the wounds were contaminated with dirt. Many such injuries have come under observation. These consist of abrasions, or incised, contused, and lacerated wounds, and also a number of suppurating wounds. None of these, however, was to be considered of a serious nature; but not a few, such as injuries to the hand, were sufficient to keep the patient from work. Instructions were given that all such wounds were to be treated in the usual manner with addition of the powder.

After quite a number of these injuries had been treated in this manner, it was quite evident that they healed more rapidly and with less disturbance than had been previously observed in those treated in the ordinary way. Since then a more careful supervision has been kept, and it has been demonstrated beyond question that the powdered serum was responsible for good results. A number of infected wounds also, due principally to vaccination and furunculosis, have been treated in like manner. The inflammation subsides, granulation occurs, and healing rapidly follows.

One observation has been made on an operation for hypertrophy of the mucous membrane of the nose. The first operation was done in the usual manner, and it required three weeks before the wound healed. A second operation became necessary. The nasal cavity was insufflated twice daily with the powdered tetanus antitoxin, and the wound healed within a week. Whether this will follow in other cases remains to be seen. It is, to say the least, quite suggestive. No injuries of major character have been observed, so it cannot be determined what effect the dried serum would have on these.

The results which have followed the application of dried serum to the wound show very conclusively that it possesses qualities other than its specific body, the antitoxin. This must be of the nature of an immune body, which, when brought in conjunction with the serum or cells in the wound, becomes bactericidal.

It may be that normal serum[2] possesses this quality and is not due to the serum of an immunized animal. It is believed, however, that, as a rule, we should expect to have better results from the serum of an immunized animal than the normal. My experience[3] with such sera demonstrates that immune horse serum, inactivated by heat, is more bactericidal than the normal serum.

In such immune serum there appears to be a body, an amboceptor, which is entirely separate and distinct from the specific immune body which is responsible for the germicidal action. This might be

termed, for want of a better name, the common immune body. It may be normally present in the blood, but it increases in amount under treatment, *pari passu* with the increase in the number of the leucocytes.

The dried serum powder seems to have some advantages over the serum, as it dissolves rather slowly and therefore is not so apt to be washed away by exudates.

It is intended to continue these observations, using other immune sera, for it may be that these may possess even better qualities than the dried antitoxin.

A CASE OF INTESTINAL OBSTRUCTION, IN A CHILD, DUE TO TUBERCULOUS PERITONITIS FOLLOWING BRONCHOPNEUMONIA.

By HENRY HUBBARD PELTON, A.M., M.D.,

NEW YORK.

CHIEF OF MEDICAL CLINIC PRESBYTERIAN HOSPITAL DISPENSARY; INSTRUCTOR IN MEDICINE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

The patient, Catherine G., was born on May 5, 1905, the first child of a mother thirty-four years of age, being delivered by the writer after a normal labor lasting about twelve hours. The weight at birth was seven pounds fourteen ounces. The mother, being absolutely unable to nurse the infant on account of lack of milk, the latter was put upon modified cow's milk. The child thrived from the first, making regular and consistent gains in weight, and on July 24 weighed eleven pounds. About this time the digestion became slightly disordered, with the result of a loss in weight to ten and a half pounds on August 7. Upon August 11 a typical attack of summer diarrhea began and lasted for two weeks; the stools were fluid in consistency, green and foul, and contained mucus in moderate amount. The treatment consisted of an initial dose of castor oil, followed by intestinal irrigations with normal saline solution after each defecation. The strength of the food was greatly diminished, but the intestinal symptoms continued for two weeks, being accompanied by occasional vomiting. The food formula was changed from time to time, but nothing was found to agree, and finally the child was put upon a mixture containing one of the proprietary foods; from this time the patient began to improve, the digestive manifestations disappeared, and a gradual and steady increase in weight was noted.

The child continued to prosper until late in January, 1906, when it suffered from a slight attack of bronchitis, which responded quickly to treatment. On February 17 it was taken ill with fever, accompanied by cough. Physical examination showed the presence of moderate rickets as evidenced by slight epiphyseal enlargements and prominence of the abdomen; percussion of the chest showed no marked dullness, but upon auscultation numerous fine, moist râles, scattered through both lungs, were heard, and the diagnosis of bronchopneumonia was made. Mild counter irritation, by means of mustard pastes applied to the thorax, and steam inhalations were prescribed. For the fever, which was at no time very high, never exceeding 103° F., occasional small doses of tincture of aconite were given, and for the cough and restlessness small doses of antipyrin and sodium bromide were administered. The strength of the food was diminished. The patient continued to eat well and lost but little flesh; the signs in the chest persisted, and after two weeks potassium iodide was prescribed, in the hope that resolution would be hastened. Following this medication, the râles became gradually fewer, but did not wholly disappear. The cough and a moderate degree of fever continued, and the possibility of tuberculous involvement of the bronchial glands and lungs was considered. There was, however, no distinct interscapular dullness. Creosote, combined with a liquid food, was prescribed, and the patient was put upon full strength food, which it digested without difficulty. The temperature still continued, reaching an evening elevation of from 100.5° to 102° F.

The condition of the patient remained as described until March 18, when an attack of emesis occurred, the vomitus consisting of mucus and curds; following this manifestation the child passed a restless night, was disinclined to take food, and vomited at intervals. The bowels moved upon the morning of the 18th. Upon the 19th the emesis continued, and there was no defecation. Intestinal irrigation resulted in the passage of a small amount of fecal matter, but no blood or mucus. Abdominal examination was difficult on account of the crying of the child, but upon one occasion satisfactory palpation was accomplished. The abdomen was distended and tympanitic but no mass was made out, and there was no especial tenderness. The patient was seen at 4 A. M. on March 20. At this time the child was manifestly worse, the face was anxious, and whatever was taken by mouth was vomited shortly afterward. The intestine was irrigated, the result consisting of a very small amount of fecal matter; a small quantity of gas was also passed. The stomach was washed and relieved of a little greenish fluid of faintly fecal odor. Digital examination of the rectum showed no abnormal condition. At this time the temperature was 99.5° F. and the pulse was 150, regular, and of fair strength. At 10 A. M. the patient vomited matter of distinctly fecal odor. The probability of intestinal obstruction and the need of operation was suggested to the parents. A consultation was agreed upon, and Dr. Alfred S. Taylor was called, who made the diagnosis of intestinal obstruction of uncertain origin, and advised immediate operation. After gaining the parents' consent with considerable difficulty, the child was removed to the Presbyterian Hospital, where laparotomy was performed by Dr. Ellsworth Eliot, Jr.

For the following report of the patient's condition upon entrance to the hospital, and the result of the operation, the writer is indebted to Dr. E. St. John Ward of the interne staff of the Presbyterian Hospital.

Physical Examination—Small infant in state of marked prostration; throat, normal; heart and lungs, normal; abdomen, full, distended, tense and tympanitic, except in flanks, where there is shifting dullness; liver dullness is obscured; general tenderness, especially upon the right side; moderate general rigidity; peristalsis audible on left side; rectal examination, negative; extremities, normal; operation, exploratory laparotomy, by Dr. Eliot. Chloroform poorly taken; position dorsal, with arms across chest; incision, four inch median laparotomy, ex-

tending about one inch above umbilicus. *Findings.*—Small intestine distended with gas and fluid, congested and dark in color; considerable amount of clear, amber, serous fluid in peritoneal cavity; peritoneum covering the gut appears somewhat granular, and is dotted here and there with specks suggesting miliary tubercles; a considerable number of fairly distinct small miliary tubercles about the cecum, where adhesions are most abundant; a few thin adhesions in various situations along the small intestine, but these are most abundant in the right iliac fossa about the cecum. At this point also is felt a hard mass in the lumen of the gut, which is movable upon manipulation. The large intestine is empty and collapsed. The intestine was carefully inspected after withdrawal from the abdominal cavity, and all adhesions were divided, special attention being paid to those about the cecum, where the constriction seemed to be. The mass above mentioned was pushed on into the transverse colon. Following these procedures, the wound was closed.

During the operation the patient's condition was poor, stimulation being necessary. After operation the child rallied temporarily, but in spite of further stimulation death took place about two hours after removal from the operating room. Autopsy was refused.

A specimen of blood taken previous to the operation showed the following conditions: There was an increase in the number of blood plates; the red cells were markedly pale, and there was a slight poikilocytosis. The differential count of the leucocytes showed 57 per cent. of polynuclear cells; 13 per cent. of transitional forms, 0 per cent. of large mononuclear cells, 30 per cent. of lymphocytes. A culture taken from the peritoneal exudate at the time of operation showed no growth.

DISINFECTION OF ROOMS BY FORMALDEHYDE. COMPARATIVE BACTERICIDAL VALUE OF VARIOUS METHODS.

By HENRY A. HIGLEY, M.D.,
BROOKLYN, N. Y.
DIRECTOR BROOKLYN DIAGNOSIS AND RESEARCH LABORATORY.

Since formaldehyde was first proposed as a gaseous disinfectant for rooms, the literature relating thereto has been multiplied and duplicated in large proportions. As the result of numerous investigations, we now know that formaldehyde gas, when placed under proper conditions and in sufficient quantity, is a powerful bactericidal agent. Such action, however, is limited to the surface of objects with which it comes in contact, its penetrating power being practically *nil*. From the inauguration of this method of gaseous disinfection up to the present time, many different forms of apparatus for producing and evolving formaldehyde gas have been devised and introduced into use. The writer has had abundant opportunity for experimental investigation with many of these forms of apparatus. The object of the work here presented was to ascertain from a bactericidal standpoint the comparative value of various methods of evolving the gas, so that from his own experience the author might be able to select therefrom, for his own use, that upon which the greatest confidence is to be placed.

Methods tested.—The original method of evolving formaldehyde gas by the incomplete oxidation of methyl alcohol over a white-hot platinum spiral has for many reasons fallen into disuse. Practically none of the apparatus now in use are constructed upon this principle. The various apparatus for producing formaldehyde gas now employed are based upon one or another of the four following principles: 1. Heating formalin (40 per cent. aqueous solution of formaldehyde gas) under pressure at a point above 100°C. 2. Heating formalin not under pressure at 100°C. 3. Heating paraform to a sufficient temperature for the evolution of the gas. 4. Mixing formalin with some other substance, and by chemical combination setting the gas free. As representative of these principles the following methods were tested in this work: 1. Trillat autoclave. 2. Heating formalin in an open vessel over a powerful flame. 3. Paraform tablets. 4. Potassium permanganate method, as proposed by Evans and Russell. 5. Lime method, as proposed by H. V. Walker.

Bacteriological technic employed.—As a test organism, the *Bacillus pyocyaneus* was used. Cotton threads one inch in length were moistened with a twenty-four-hour bouillon culture of this organism. These threads were air-dried for forty-eight hours. After drying, ten threads for each experiment were kept as controls, and the balance (known as "test threads") were exposed to the gas for the time indicated in the tables below. After this exposure, each control and test thread was placed in a tube of sterile Dunham's peptone solution and incubated at 37.5°C. for four days. At the expiration of this time a green color in the tube was regarded as signifying growth of the *Bacillus pyocyaneus*. In those tubes in which no green color was thus produced the *Bacillus pyocyaneus* was regarded as dead. The room used for exposure to the gas was of a capacity of 786 cubic feet. Before the exposure all openings around windows, doors, etc., were carefully plugged with raw cotton.

Conclusions.—The annexed tables show that by far the best comparative bactericidal results were obtained by the lime method. The writer would state, in closing, that the bacteriological technique used in this work was selected by him after extended experience with other methods as recommended by various observers as that by the use of which the smallest error is possible. Whether or not his opinion in this respect be correct has no effect upon the validity of these observations, since all the methods were subjected to precisely the same technique. The comparative value of the various methods, which was the author's intent, was therefore correctly obtained.

The results obtained are shown in the following tables:

TABLE I.

Method	Amount of formalin or paraform used	Air space of exposure room	Length of time required to evolve gas in exposure room	Time of exposure to gas from beginning of evolution	No. of controls	No. of tests	Per cent. death of controls	Per cent. death of tests
Autoclave	6 oz.	786 cu. ft	15 min	6 hrs	10	500	0%	42.4%
Open boiling of formalin	6 oz.	786 cu. ft.	20 min.	6 hrs	10	500	0%	59.2%
Paraform tablets.	1000 gr.	786 cu. ft	1½ hrs.	6 hrs	10	500	0%	21.6%
Potassium permanganate method	6 oz.	786 cu. ft.	2 min.	6 hrs	10	500	0%	62.8%
Lime method	6 oz.	786 cu. ft.	3 min.	6 hrs.	10	500	0%	91.4%

TABLE II.

Autoclave	6 oz.	786 cu. ft	15 min	4 hrs.	10	500	0%	31.2%
Open boiling of formalin	6 oz.	786 cu. ft	20 min	4 hrs	10	500	0%	41.2%
Paraform tablets	1000 gr.	786 cu. ft.	1½ hrs	4 hrs	10	500	0%	16.2%
Potassium permanganate method	6 oz.	786 cu. ft	2 min.	4 hrs	10	500	0%	54.6%
Lime method	6 oz.	786 cu. ft	3 min.	4 hrs	10	500	0%	86.2%

62 Schermerhorn Street.

A CASE OF PERFORATIVE APPENDICITIS CAUSED BY A FOREIGN BODY.

By FRANK H. JACKSON, M.D.,

HOULTON, MAINE.

The following case, while presenting nothing new in way of diagnosis or treatment, has a somewhat uncommon etiology, which fact seems to warrant its report.

DaCosta, in his handbook on surgery, says that although cases of appendicitis from the entrance of foreign bodies into the lumen of the tube do occur, with the exception of the so-called enteroliths, they are rare. Pick speaks of orange seeds, berry stones, etc., but remarks on the infrequency of such cause. Bryant says that "89 per cent. contained fecal or other foreign material." What the "other" was he neglects to state. Osler says that "foreign bodies are by no means frequently met with and," quoting Fitz, records 12 per cent. in 150 cases. In the routine work of postmortems in Montreal he found two cases of foreign bodies in ten years. Cases are on record in which the common pin has been found. Holt gives one case of his own and reports two more. Tiffany in the Reference Handbook of the Medical Sciences, says that "the presence of a foreign body is rare" excepting fecal concretions. The similarity between a fecal concretion and a date stone is often a cause of error.

J. B., aged 23; single; sawmill operative. Uses alcohol to some excess. Never has had any serious illness that he can remember. Has always worked hard since a boy. About a year and a half ago had what he called a severe attack of "indigestion." His bowels were constipated at the time and he took cathartics to obtain relief. He described the pain as starting in the pit of his stomach and then going over to his right side. Following the first attack he has had more or less pain in his right side, and says that if his bowels are constipated the pain is very much worse. During the past eighteen months he has had several attacks of this pain, which has forced him to quit work at the time, but that he never has consulted a physician.

The present illness began June 12, although he had not been feeling well for some few days. He was suddenly seized with a terrific pain in the stomach that caused him to fall on the ground. The pain was described as knifelike and caused him to cry out with the agony. He thought the pain was another attack of indigestion, as his bowels had been constipated for some few days. He reached his boarding-house with some difficulty and applied hot cloths moistened with turpentine to the abdomen. The pain, which was at first in the pit of the stomach, now was in the right side, and was seemingly getting worse. As the patient was in a place that was unsuitable for medical care, he crawled out of bed and came to Houlton on the train, a distance of some thirty miles. The pain on the journey was most severe and he was intensely nauseated, but did not vomit. I saw him about 4 P.M., and found the following: Patient was of good build and fairly well nourished. His face was pale and covered with a cold, clammy sweat. Temperature (mouth) 99.5°, respiration 22 and thoracic, pulse 120, wiry and intermittent. Tongue was coated and his breath foul. The abdomen was distended and the patient lay with thigh flexed, as by that posture he could lessen the pain. Percussion gave a general note of tympany. There were loud, gurgling râles in the right iliac fossa. The lower quadrant on the right side of the abdomen was absolutely rigid and was painful. The maximum point of the pain was a little below and to the inner side of McBurney's point. Pain was not referred to the testicle.

A diagnosis of an exacerbation of a chronic adhesive appendicitis was made and operation advised. This was performed June 13. On opening the peritoneum a large amount of bloody serum poured out that rendered inspection difficult for some few minutes, despite the use of gauze to absorb the same. The omentum was highly congested and was adherent to the cecum and completely enveloped the appendix. On separating the adhesions I felt something catch on my glove. Inspection disclosed a pointed article projecting through the omentum. I tore through the omentum and the foreign body could be seen as it pierced the gut wall at the junction of the cecum and appendix. The omentum was separated from the gut and the appendix tied off and removed. Traction on the foreign body with a hemostat allowed its removal. The stump of the appendix was inverted and a double Lembert stitch taken that included the perforation. The post-operative history is of no import, and, barring a minute stitch abscess, recovery was ideal. The patient went home on the eleventh day and was seen on August 30, and said he was in perfect health. His bowels since the operation have been regular. The appendix was thickened, and there was an old stricture about half way between the tip and the base. Its cavity was filled with a dark bloody material about the consistency of tar. The foreign body was a fish bone an inch and a quarter long and its thickest diameter was the size of an ordinary knitting needle.

The Preventive Treatment of Senile Cataract.—Oscar Wilkinson does not believe in allowing a patient with beginning cataract to go untreated until blindness is fully developed. He has studied these cases very closely and concludes that cataract is a result of a disease of the eye, or some constitutional disorder, and deserves to be treated the same as any other disease. He does not look upon the cataractous lens as an excessive change due to age. Cataractous changes are "chemical, not morphological." Treatment of cataract should be both constitutional and local. The former treatment should consist in caring for any condition that is found to be interfering with the patient's general health. Every organ in the system that may possibly be diseased should be investigated. Gouty, rheumatic, or lithemic conditions should all receive proper treatment. The writer has found the digestive apparatus to be one of the most frequent sources of poison to the general system. After the general practitioner has corrected any special disease, the writer prescribes alteratives, tonics, and a free quantity of alkaline water, especially lithia water. The general tonics indicated are iron, quinine, strychnine, and gentian. The condition of each patient will indicate which of these tonics is demanded. Exercise in the open air is essential. Associated ocular diseases also require attention. The errors of refraction and accommodation must be corrected. The writer believes that the wearing of a proper lens does more than any other remedy for low-grade inflammations of the uveal tract. Such patients should use their eyes sparingly, for the cataractous eye is a diseased eye and it needs rest. The writer believes that the preventive phase of cataract treatment has not yet come in for its share of attention from competent men.—*Gaillard's Southern Medicine.*

MEDICAL RECORD.

New York, October 20, 1906.

FRUIT AS A FOOD.

OF late years much has been written concerning vegetarianism. Not only has the literature on vegetarianism been extensive, but many have adopted its principles and have lived on a diet from which meat has been excluded. In Great Britain this practice has had and still has a great vogue, so much so that vegetarian restaurants flourish in many cities, and especially in London. Some physicians, too, in England advocate the exclusive use of a diet devoid of meat, arguing that it is healthier than the ordinary diet to which civilized individuals have been accustomed for many centuries; and they point out that the Roman soldiers subsisted chiefly on food composed mainly of fruits and that the Japanese of the present day are more or less vegetarians. In a pamphlet reprinted from the Year Book of the Department of Agriculture for 1905, Dr. C. F. Langworthy of the Office of Experiment Stations deals with fruit and its uses as food in a comprehensive and interesting fashion. The composition of various fruits is discussed, and a table is given in which will be found the average composition of fruits and fruit products. These data show that fresh fruits are in general dilute foods—that is, the proportion of water which they contain is large compared with the total amount of nutritive material. In the majority of fruits and fruit products the carbohydrates are the food constituents most abundantly represented. The proportion of nitrogen-free extract varies greatly, being lowest in the fresh and highest in the dried and preserved fruits. The principal sugars in fruit are cane sugar, grape sugar (glucose), and fruit sugar (levulose), the last two, designated invert sugar or reducing sugar, being usually present together in equal quality. The acid in fruits varies within rather wide limits, 1 to 2 per cent. being reported on an average in such fruits as apples, pears, plums, strawberries, etc., and as high as 7 per cent. or more in lemon juice.

Extended investigations were undertaken at the California Experiment Station by Prof. M. E. Jaffa, the work as a whole being carried on in cooperation with the nutrition investigations of the office of experiment stations. Studies were made with persons who had subsisted on a fruit diet for many years and with persons who were accustomed to a vegetarian and to an ordinary diet. These individuals were of different sexes and ages. The results obtained from the first series of studies which were made on women and children showed a range, calculated on the basis of amounts eaten per individual per day, of 47 to 80 gm. of protein, and 1,850 to 2,805 calories of energy, the cost of the daily food ranging from 21 to 55 cents per individual per day. In the next series of studies young and old men were the subjects of the experiments, and it was found that the protein supplied by the daily diet ranged from 40 to 85 gm. and the energy from 1,712 to 3,305 calories, the average being 62 gm. and 2,493 calories, the cost ranging from 18 to 47 cents per person per day. These studies covered from twenty to twenty-eight days, and the daily food consisted of different combinations of fruits and nuts, of which the following day's ration may serve as a sample: 475 gm. apples, 110 gm. bananas, 850 gm. oranges, 5 gm. dates, 2 gm. honey, 10 gm. olive oil, 55 gm. almonds, 70 gm. pine nuts, and 50 gm. walnuts. The result of these investigations was to show that, while they were too limited to warrant the foundation of any very definite conclusions, the statement might be confidently made that fruit and nuts should not be looked upon simply as food accessories, but should be considered a fairly economical source of nutritive material.

Experiments were also conducted by Professor Jaffa to determine the digestibility of fruit, and although sufficient data have not been gathered to justify dogmatic statements in regard to this point, enough, he says, has been done to show that they are thoroughly digested and have a higher nutritive value than is popularly attributed to them. With respect to the relative digestibility of different fruits, evidence is too scanty to make any exact statements, but apparently stomach digestion is influenced by the nature of the fruit and its stage of ripeness. Beaumont states that mellow sour apples require two hours for digestion in the stomach, and mellow sweet apples ninety minutes. Another observer has noted that about five ounces of raw ripe apple requires three hours and ten minutes for digestion in the stomach, but states that if the fruit is unripe, and consequently contains a high proportion of cellulose, a much longer time may be required. Apples are viewed, from an economical and nutritive standpoint, as the best of all fresh fruits, especially when eaten uncooked, while of dried fruits dates and raisins rank the highest.

The conclusions reached as a result of the studies were that, in general it may be said that fruits are wholesome, palatable, and attractive additions to our diet, and may be readily made to furnish a considerable part of the nutrients and energy required in the daily fare. Fresh fruits are dilute foods and closely resemble green vegetables in total nutritive value, but dried fruits and many preserves are much more concentrated, comparing favorably with some of the cereals and other dry vegetable foods in the amount of total nutrients and energy which they supply per pound. Characteristic chemical constituents of fruits are carbohydrates, and so they are naturally and properly used in a well-balanced diet to supplement foods richer in protein, such, for example, as cereal grains, legumes, nuts, eggs, dairy products, meats, and fish. Intelligently used, fruits constitute a most valuable part of a well-balanced diet and may profitably be eaten in even larger quantities than they are at present by the majority of mankind.

THE TREATMENT OF TETANUS.

In the *Annals of Surgery* for September are two articles on the treatment of tetanus. The first of these deals with the therapeutic value of the antitoxin treatment of tetanus and is written by Dr. Nathan Jacobson of Syracuse, N. Y., and Dr. Herbert D. Pease, Director of the Antitoxin Laboratory, New York State Department of Health. It is pointed out that the bacillus of tetanus can develop but little, if at all, below 60° F., which, it may be assumed, accounts for the fact that the organism is more active during the summer months. Another important point referred to by the authors is that the bacillus is a frequent habitant of the intestinal tract of animals, especially of horses and cattle, and consequently all wounds received in stables or contaminated with animal discharges are particularly to be feared. Again, tetanus can readily follow unclean surgical procedure, and therefore a sufferer from tetanus should be completely isolated from all other surgical patients.

After describing at some length the conditions of infection, the distribution of the tetanus bacillus in the body, the period of incubation, and the relation of the toxin to the nervous system, the authors proceed to discuss treatment by tetanus antitoxin generally. Stress is laid upon the fact that antitoxin, to be of the greatest service, must be administered before the motor nerves have absorbed any toxin. Therefore the serum should be administered as soon after the infliction of the injury as possible and should be given to every person who has sustained an injury in which dirt, manure, or other foreign substances could possibly have been carried into the wound. Injuries involving the nerve-trunks should be treated with antitoxin locally as well as subcutaneously, in order to prevent the direct absorption of toxin by such injured nerves. For this purpose either liquid or dried antitoxin is suitable. As to the special methods of injection, the intracerebral method has nothing particularly to recommend it, in the opinion of the authors, nor is it free from danger. The injection of antitoxin into the subdural space finds little favor, while it is pointed out that the attempt to neutralize the toxin present in the large nerve trunks by the injection of antitoxin into them probably only prevents the absorption for the time being, and it is even doubtful whether it is possible to neutralize any considerable portion of the toxin in a given nerve by intraneural injections.

The conclusions come to by Drs. Jacobson and Pease are that, as a prophylactic measure, the injection of antitoxin merits our fullest confidence, but as regards the treatment of tetanus after the disease is fully established, we are forced to admit that as yet no method has been discovered whereby it can be administered so as to reach effectively the toxin not free in the blood or lymph. In the author's review of cases of tetanus treated by antitoxin it appears that subcutaneous injection was the method most generally used and that the mortality of the patients who were thus treated was less than that resulting from other methods.

The second article relating to the treatment of tetanus is by Dr. Joseph A. Blake of New York, and treats of the therapeutic virtues of magnesium sulphate. The use of magnesium sulphate as a therapeutic agent in tetanus was suggested by the discovery by Dr. S. J. Meltzer of the marked action of this salt, when applied to nerve-tissues, in inhibiting both afferent and efferent impulses. As noted in the Medical Record of December 16, 1905, Meltzer found that one cubic centimeter of a 25 per cent. solution of magnesium sulphate to every twenty-five pounds body weight was sufficient, when injected into the spinal canal, to produce surgical anesthesia. Absorption from the spinal canal, however, is fairly slow, and definite action upon the nerve-trunks may be obtained, while the general effects upon the higher centers may not manifest themselves for several hours or may be wholly absent. In the case of lumbar injections into the subdural space, magnesium sulphate acts directly upon the nerve-trunks at the site of injection, and as it diffuses itself upward along the cord its paralyzing effect extends to the trunk and upper extremities, diminishing, however, in intensity as it progresses. Age and sex appear to have a direct bearing upon its action, and Dr. Blake thinks that, so far as is known, children are the most susceptible, and women more so than men.

Up to the present time but four cases of tetanus have been treated by this method, so that it is far too early to dogmatize as to the effect of magnesium sulphate on the course of tetanus. Dr. Blake's impression of the drug is that, although we cannot be certain of its effect, yet it is reasonably safe and offers us a means of modifying the convulsions and of relieving pain more satisfactorily than any other drug. Moreover, it produces anesthesia, which may be taken advantage of for intraneural or other injections of tetanus antitoxin and for local treatment of the site of the infection.

JEJUNOSTOMY FOR THE HYPEREMESIS OF PREGNANCY.

Hyperemesis of pregnancy is a condition for which an untold number of remedies have been suggested, the most effective of which seem to be those which are directed to the eliminative channels of the body, for undoubtedly the largest proportion of cases are due to autointoxication. But there are instances in which the cause for the disturbance is not a toxemia proper, and a nervous element is probably at fault, which, for want of a better name, has been called a gastrointestinal hysteria. In addition to these there is another class of cases in which some disease of the stomach is present, and the vomiting which is caused by the latter is greatly aggravated by the advent of the pregnancy. An instance of this kind is reported by Brunon and Jeanne (*Bulletin médical*, No. 55, 1906), in which the patient for the period of a year had been subject to attacks of repeated and rebellious vomiting, which became greatly aggravated by an unrecognized pregnancy. On account of the progressively increasing emaciation a jejunostomy was suggested and carried out, with an immediately favorable result. This continued for a period of six weeks, during which the pregnancy was diagnosed, and then the patient withdrew from observation. Apparently uncared for, the vomiting returned, and then the uterus was emptied, but the

patient died from exhaustion shortly after. The favorable result which attended jejunostomy in this instance is, of course, insufficient to recommend the operation as a routine in such cases; but the fact that the symptoms completely disappeared after it was done is noteworthy, and the procedure may be carried out with comparatively little shock to the patient, if necessary, under local anesthesia.

Although the performance of jejunostomy is a very radical suggestion, the fact must be borne in mind that the induction of abortion is, in advanced hyperemesis, an operation which only too often results fatally for the mother, while, as already noted, a jejunal fistula may be produced with comparatively little shock. As the vomiting usually stops spontaneously at or before the sixth month, the patient may thus be tided over by this means, and the sacrifice of the child's life not rendered necessary.

Arterial Disease after Adrenalin Injections.

It has been found that the intravenous injection of adrenalin in rabbits may be followed by extensive change in the aorta and the larger vessels. This has been determined to consist of a localized destruction of the smooth muscle fibers of the media, accompanied by a rapid calcification and other characteristic alterations in the elastic-tissue elements. This results in a narrowing of the lumen of the vessel and a diminution in its elasticity which is subsequently followed by a compensatory new growth of elastic fibers and of muscle and endothelial cells in the intima. Finally there is produced as the net result of these changes a series of aneurysm-like bulgings of the vessel wall. The adventitia and the vasa vasorum do not seem to be involved in the process at any time. Erb, who presents a very interesting communication on this subject in the *Archiv für experimentalle Pathologie und Pharmakognosie,* Vol. 53, 1906, claims that these findings show there is no actual similarity between this condition and the arterial sclerosis which is found in the human subject. There is no sclerosis in the sense of a thickening due to proliferation of the intima nor an atheromatous process. But there is apparently an analogy between the condition described in the rabbit after intravenous adrenalin injection and the calcification of the media as found in the large arteries of the extremities in man. Erb believes that this vascular disturbance is not due to an increase in blood pressure or to nutritive changes brought about by spasm of the vasa vasorum, but is due rather to a direct toxic effect of the adrenalin on the smooth muscle cells of the vessel wall.

Oatmeal Diet in Diabetes.

A few years ago von Noorden made the suggestion that oatmeal in large quantities be given to patients suffering from severe diabetes, and claimed that by this means the glycosuria and acidosis were favorably influenced. The oatmeal was cooked with butter and water, and then an egg albumin preparation was added, so that the patient received about 3,000 calories and a sufficient amount of albumin to satisfy the albuminoid demands of the body. Lipetz (*Zeitschrift für klinische Medizin,* Vol. 56) has made some further tests of the method, giving oatmeal to a patient who was free from any glycosuric symptoms. An examination of the feces disclosed a large increase in the number of the bacteria, pointing to greater intestinal fermentation. In another case, a severe one of diabetes, the diet was absolutely without effect—on the contrary the sugar excretion and the acidosis were increased. In a less advanced case the sugar was increased, but the acidosis diminished. Other cases were subjected to the same régime, but without attaining the good results claimed by von Noorden. In explanation of this fact Lipetz suggests that the favorable effects obtained by the originator of the diet scheme in question were due to the nonabsorption of the ingested carbohydrates, although the latter had been taken in such large amounts. This is simply another instance in which the contentions of one man, here seemingly rather extravagant, fail to be substantiated by another under apparently similar conditions.

Strabismus and Epilepsy.

We have learned in the last few years a great deal about the influence of visual disturbances on the production of functional diseases, until there are but very few left which fail to come under this category in some form or other. Prof. Schoen of Leipzig (*Wiener klinischtherapeutische Wochenschrift,* September 9, 1906) is convinced that there is also a direct connection between vertical squint and epilepsy, and claims to have found this defect in a large percentage of the inmates of a German institution for epileptics. In addition to the epilepsy there were other symptoms, such as migraine, vertigo, nausea, gastric and cardiac complaints, neurasthenia, and hysteria, which are often associated with eye disturbances. Epileptic convulsions are known to be due to cerebral irritation, and Schoen claims that in uncomplicated cases the irritation is due to eyestrain, usually that due to vertical strabismus of congenital origin. The constant effort on the part of the child to bring the visual axes into the same plane results in a condition of tension which in the course of time brings about nervous disturbances of an intermittent explosive character and permanent changes in the brain. Schoen believes that proper glasses will in such cases bring about a total cure, but they must be applied early, as soon as the true condition is determined, and must be worn constantly.

News of the Week.

Southern Medical Association Organized.—After an existence of eighteen years, the Tri-State Medical Association of Tennessee, Alabama, and Georgia, at its last meeting, held at Chattanooga on October 5, relinquished its charter, and was replaced by the Southern Medical Association. The new organization comprises Mississippi, Tennessee, Georgia, Alabama, Florida, and Louisiana, and it is expected that the Carolinas and Kentucky will ultimately be included. The newly elected officers are: *President,* Dr. H. H. Martin of Savannah, Ga.; *First Vice-President,* Dr. Mack Rogers of Birmingham, Ala.; *Second Vice-President,* Dr. J. B. Cowan of Tullahoma, Tenn.; *Third Vice-President,* Dr. J. R. Tackert of Meridian, Miss.; *Secretary,* Dr. Raymond Wallace of Chattanooga; *Treasurer,* Dr. Y. L. Abernathy of Chattanooga.

Yellow Fever in Cuba.—Three new cases of yellow fever have been reported from Havana, and several others have appeared at Cienfuegos and Guines. Vigorous measures have been taken to prevent the men of the Marine Corps from becom-

ing infected. Ten barrels of oil of citronella have been sent to Cuba, and every marine on guard duty will be supplied with a bottle of this oil to be used in protecting himself against mosquitos. All the marines in Cuba are supplied with mosquito netting for their beds, and head nettings are also available for their use. Water filters have also been sent to Cuba, and the officers in the island have been urged to caution the marines against the use of unfiltered water.

International Cancer Conference.—At the International Cancer Conference held at Heidelberg and Frankfort-on-the-Main during the first days of the month, the most notable feature was the formal opening of the new Cancer Institute at Heidelberg, of which Professor Vincent Czerny is the director. After holding the chair of surgery in the University of Heidelberg for many years, Czerny, on October 1, resigned his post in order to carry out his long-projected plan of devoting the remainder of his life to the study of cancer. The institute has been planned in all its details by Czerny, who also contributed largely to the fund necessary for its erection and equipment. It comprises a complete hospital organization, together with elaborate laboratory facilities for the most advanced research work.

Hydrophobia in Germany.—In the year 1905 368 cases of injury through rabid or suspectedly rabid animals were officially reported in Prussia. Of the patients 71.2 per cent. were males and 28.8 per cent. were females. The injuries were for the most part caused by dogs, though seven were inflicted by cats, four by cattle, and two by horses. In five cases there was no bite, infection occurring in the course of tending the rabid animal, and in one instance at the autopsy on such an animal. Of the 368 patients, 323, or 87.8 per cent., were treated at the Pasteur Institute in Berlin; of the forty-five others twenty-two were treated at home and twenty-three received no treatment whatever. Eleven deaths occurred, three of the patients having received Pasteur injections, and the others having been treated at home or left untreated. That is, the 323 inoculated patients exhibited a mortality of less than 1 per cent., while of the forty-five others 17.8 per cent. died.

Increase of Immigration.—During the six months ending September 30, 682,560 immigrants were admitted to this country, as compared with 595,484 in the same period of last year, and 458,683 in 1904. The figures for this year indicate an increase of 49 per cent. over the immigration in 1904. In the six months named, 9,236 persons were debarred. Of the total immigration in that period 157,240 persons came from Russia. During the month of September 95,341 immigrants were admitted and 1,052 deported.

Professor **Ernest Wertheim** (Professor of Gynecology in the University of Vienna) recently spent a week in Chicago as the guest of the Chicago Gynecological Society. He gave clinics at the Post-Graduate Medical School and Hospital, and the Presbyterian Hospital. He was entertained by Dr. Gustav Kolischer at a dinner given at the Chicago Beach Hotel, and by Dr. Franklin H. Martin at a luncheon at the Union League Club. A banquet was given in his honor, October 10, by the Chicago Gynecological Society, at the close of which he read a paper before a joint meeting of the Chicago Medical and Chicago Gynecological Societies, entitled "Radical Abdominal Operation in Carcinoma of the Cervix Uteri."

Dr. Alfred Schalek of Chicago has been appointed Professor of Dermatology and Genitourinary Diseases in the Medical College of the University of Nebraska, Omaha, and has moved to that city.

Malaria in Greece.—The excessive prevalence of malaria in Greece is said to be checking the development of the country to a serious degree. Out of a population of 2,500,000 there have been 250,000 cases of malaria annually, with about 1,760 deaths. Last year the number of cases increased to 960,000, and the deaths to 5,916. Prof. Savas, of the University of Athens, and physician to King George, is initiating a movement to deal with the plague, and has recently been to Liverpool to consult with Dr. Ronald Ross of the School of Tropical Medicine regarding the best means of mosquito extermination.

Contract Work in the Oranges.—The physicians of the Oranges have united in an effort to abolish contract practice, and at a recent meeting of the Practitioners' Society of the Oranges the members agreed not to enter into obligations of this sort.

Resolutions Against Newspaper Doctors.—At a meeting held September 25 the Decatur (Ill.) Medical Society decided that the names of members should not be mentioned in connection with medical matters in the daily press, and that, if such notice should appear, the physician in question would be requested to explain at the next meeting of the Society.

Society to Abate the Smoke Nuisances.—According to the *American Machinist* about forty city smoke inspectors held a convention in Detroit recently for the purpose of forming a National Association of Smoke Inspectors.

Insane Journalism.—A dispatch from Vienna announces that the inmates of the new insane asylum at Maueroeling, one of the largest in the world, have started a newspaper. The first number declares that it is published "by the mad for the mad," but the contents are said to be surprisingly like those of most papers.

Accidental Death at 117 Years.—The death is reported from Frankfort, Ky., of a colored woman named Anne Jane Mitchell, who was fatally burned at the age of 117 years on October 11. Her husband, who died recently, is stated to have been a centenarian.

The Yield of Radium.—It is stated that the radium mines at Joachimstal, in Austria, recently supplied the Vienna Academy of Science with ten tons of uranium ore, and this has yielded a very large amount of radium, which is to be used for research. The mines are being converted into a radium cure resort. A local laboratory for producing radium salts has been established, and the springs are serving as medicinal baths.

Presidio Hospital Burned.—The large two-story military hospital at the Presidio, Monterey, Cal., was burned on October 14, and damage amounting to $50,000 was caused. The fire was started by the explosion of a tank of gasoline at the rear of the building. The patients were all removed in safety.

County Hospital for San Jose.—The supervisors of Santa Clara County, Cal., have approved the plans for a new county hospital to be built at San Jose at an expense of $50,000.

Long Island Throat Hospital and Ear Infirmary.—At the seventeenth annual meeting of this

organization, recently held, Dr. C. T. Schondelmeier was elected president for the ensuing year. The report of the surgeon-in-chief, Dr. D. Morris Woolley, showed that there were treated during the last year 496 new cases, with 1,800 revisits, making a total of 2,296 cases treated. There were given 1,080 free prescriptions, and 337 operations were performed upon the nose, throat, eye, and ear.

Suffolk County (N. Y.) Medical Society.—The annual meeting of this society will be held at Riverhead, October 25, 1906. Officers will be elected under the new by-laws. The president is Dr. W. H. Ross of Brentwood, and the secretary is Dr. Frank Overton of Patchogue.

Council Bluffs (Neb.) Medical Society.—At the annual meeting of this society the following officers were elected: *President,* Dr. Daniel Jackson; *Vice-President,* Dr. R. B. Tuffs; *Secretary,* Dr. J. H. Cleaver; *Treasurer,* Dr. F. W. Dean.

Obituary Notes.—Dr. Randall Croft Stoney of San Francisco was instantly killed by being crushed in a car accident in that city on October 1. Dr. Stoney was a man of more than ordinary ability, and had attained unusual prominence for a man of his age. He was just thirty-one years old, and but recently married. He was born in Charleston, S. C., studied there and in New York, graduating from the Medical College of North Carolina in 1897, and served in the Spanish war. He was a member of the California State and San Francisco County medical societies, and assistant in gynecology at the Oakland College of Physicians and Surgeons.

Dr. Henry A. Laurent of this city died on October 12 of nephritis, at the age of forty-three years. He was born in Alsace-Loraine and was educated at Heidelberg. He came to this country when he was twenty-three years old, and obtained his degree in medicine at the University of New York.

Dr. Guido Katzenmayer of this city died on October 13 after an illness of several weeks' duration. He was born in Germany in 1832, and was educated at Heidelberg and Würzburg. He came to New York in 1853, and practised medicine here until his death, except from 1865 to 1878, during which time he was abroad.

Dr. Robert Schmeltzer of Brooklyn died on October 11 at the age of fifty-five years. He was well known as an oculist, and was prominent in German social life.

Dr. John W. Dryer of Milwaukee, Wis., died on October 5 in Reedsburg, at the age of forty years. He was graduated from the Milwaukee Medical College in 1901, but for the past two years had been unable to practise, owing to illness.

Dr. Morse Stewart of Detroit died on October 9, at the age of eighty-eight years. He was born in Penn Yann, N. Y., and received his education at Hamilton College and at Geneva Medical College, from which he was graduated in 1840. He came to practise in Detroit shortly afterward, when the city had little more than 10,000 inhabitants.

Dr. Anthony J. Weitenberner of Detroit died on October 8 of typhoid fever after a three weeks' illness. He had practised in the north end for about eight years.

Dr. G. S. Armstrong of Spokane, Wash., died on October 2, at the age of forty-eight years, after an illness of several months' duration. He had resided in Spokane six years, coming there from Northport, Wash. Previously he had practised in Olympia. He was a member of the State Board of Health, and was an active member of the Washington State Medical Association.

Dr. T. J. Scott of Alvin, Tex., met with death by accidental drowning in Galveston Harbor on October 1. Dr. Scott was sixty-eight years of age, and had practised in Alvin for many years.

Dr. James Stewart of Montreal died on October 6, as the result of an apoplectic stroke. Dr. Stewart was born in 1846, and, after receiving his medical degree from McGill University at the early age of twenty-two years, spent several years in study abroad. He was admitted a licentiate of the Royal College of Physicians and Surgeons in 1883. He had practised many years in Montreal, and was recognized as an authority on nervous diseases. Up to 1891 he was professor of materia medica and therapeutics at McGill, and in that year succeeded Dean Ross in the chair of clinical medicine. In 1903 he was elected president of the Association of American Physicians.

Correspondence.

DIGESTION OF STARCH BY INFANTS.

To the Editor of the Medical Record:

Sir: In a friendly spirit, and anticipating that errors in my own logic may be pointed out, I venture to offer some criticism of an article by Dr. J. H. Lopez, on "Examination of the Feces of Twenty-five Starch-fed Infants," in your issue of September 29.

According to the author, we have the following results: Class A, fed on wheat gruel, containing 1.5 per cent. of starch, feces, 0.1 per cent. Class B, fed on arrowroot, containing 2.5 per cent. of starch, feces, 5.1 per cent. Class C, fed on wheat and barley, containing 2 per cent. of starch, feces 2.7 per cent. Aside from purely analytical difficulties, which render it impossible to draw conclusions as to the digestion, unless considerable differences exist between the income and outgo, the destruction of starch by bacteria must be discounted. Again, any such comparison should state the actual quantities of gruel administered and feces passed. Excepting the first class, the food has evidently suffered a relatively greater abstraction of water than of starch, and in Class B, if the feces were half the volume of the food, there would be no absorption of starch; if a quarter the volume of the food, there would be a waste of 50 per cent. of the starch, and so on, without regard to destruction by bacteria. Another very important point is that the investigations were apparently being carried on in a series of starving babies, who should have extracted almost every particle of nutriment. Babies from two to six months old normally consume from 900 to 1,150 c.c. of milk daily, corresponding approximately to from 35 to 45 grams each of proteid, fat, and carbohydrate. The author does not state how much the babies received, but it is scarcely conceivable that the bulk of gruel exceeded 2,000 c.c. daily. If this amount was exceeded, the gain in nutriment would be more than counterbalanced by the mechanical disadvantage. On the hypothesis that 2,000 c.c. of gruel was given daily, Class A received 30 grams of carbohydrate, about 9 grams of proteid, and practically no fat; Class B, 50 grams of carbohydrate and practically nothing else, and, for Class C, not enough data are at hand, although the ratio would probably be about the same as for A. The article seems to imply that the "gruels" were water gruels. At least, arrowroot gruel is commonly made without milk, and for Class C, wheat and barley water are specified. If milk or other ingredients of organic nutritive value were incorporated in the gruels, the ratio would, of course, more nearly approach the normal. Still, even if 50 per cent. of milk were used and the daily normal bulk were doubled, as has been estimated, we should have merely an increase of carbohydrate in Class B and of carbohydrate and, to a less degree, of proteid in Class A. Now, if water gruels were used, representing a very inadequate total amount of nutriment, the fact that anything more than a trace of starch remained in the feces confirms the old idea that young infants cannot efficiently digest starch. According to time-honored teaching, the sixth month is taken to represent the approximate dividing line between inefficient and efficient starch digestion. Thus, the inclusion of one or two infants of about this age, in each series, would vitiate the premises, so far as conclusions bearing upon this point are concerned.

It may very well be that the author is quite justified in drawing the conclusion that he does, regarding the efficiency of starch digestion in infants, but he has not presented his evidence to warrant his conclusion. I would, therefore,

suggest that he state, for each infant, the age, bulk of ingesta, content of ingesta in starch or other carbohydrate, proteid, and fat—average analysis tables for the various foodstuffs used would be sufficiently exact—bulk of feces, and actual amount of starch or sugar found in the feces.

A. L. Benedict, M.D.
Buffalo.

TRACHOMA IN SCHOOL CHILDREN.

To the Editor of the Medical Record:

Sir:—During the school session quite a number of trachoma cases attend the various eye clinics for treatment, and since the method of school inspection by the Health Department has been in vogue the disease can be seen early and in all its stages. Trachoma, when seen early, is amenable to treatment, but it takes time. In the clinic I have seen very severe cases in which operation has been refused result in cure under blue stone. The worst cases are met with in those children who have not as yet attended school. These cases are neglected, the parents often attributing the trouble to a cold. The inevitable result of this neglect is seen in corneal ulcers, opacities, and keratitis, with defective vision later on. It is interesting to note that trachoma is rare in mountainous regions, and that negroes are less affected (a fact I have noticed at the clinic). There is a good deal of controversy as to whether trachoma is contagious from the beginning, some holding that it is not contagious until a discharge appears. Personally, I have seen four or five members of a family affected when there was no discharge and few granulations were present.

There are two forms of the disease, acute and chronic. The former is rare; it is accompanied with a mucopurulent discharge which absorbs the granulations and thus cures itself. The chronic form is more common. By some the disease is believed to be due to a microorganism (the trachoma coccus). It is common to see children with severe cases of trachoma in whom no other complications are present, the cornea is clear, and also the conjunctiva; why that is I cannot state. As a result of the new tenement laws in this city and the education of the parents through the school children, trachoma is diminishing, and although the disease may never be stamped out, yet I believe that statistics will show in the future a marked decrease throughout the city, especially among school children.

Abraham A. Goltman, M.D.
1409 Prospect Avenue, New York.

SOME OF THE USES OF CARBOLIC ACID.

To the Editor of the Medical Record:

Sir:—Having had, for the past eight years, some very satisfactory and unusual results from the use of carbolic acid, I send the following, feeling that the treatment ought to have a wider opportunity than can be given in a country practice.

I have used carbolic acid (liquified crystals) in fourteen consecutive cases of diphtheria. The acid is applied by saturating a piece of absorbent cotten (so it will not drip), fixed to a cotton holder, and smearing the tonsils till the surface turns white. This operation is to be repeated every day—sometimes, lightly, both morning and night. In four or five days the cure is complete. Every case of diphtheria I have ever had has terminated in recovery under this treatment. I have used the same treatment in tonsillitis, in a great many cases with perfect results, sometimes aborting the disease with one application. Enlarged tonsils and uvula (chronic inflammation) can be cured in the same way. I have also removed adenoids in the same manner.

Papules, furuncles, and carbuncles can be aborted if touched before suppuration has occurred. I have injected several encysted tumors of the back with pure acid and have seen them disappear without any pain or inconvenience to the patient. I have used a 50 per cent. mixture of the acid with water (on cotton, with holder) and thrust the cotton through a polypus of the nose, and also through uterine polypi, and have destroyed them with one or two treatments. Warts may be removed by touching with carbolic acid on a dull-pointed stick.

Toothache can be relieved almost instantly by applying about one-half a drop to the exposed nerve with a camels-hair pencil.

I have touched the tonsils lightly in whooping-cough, scarlatina, and in some cases of tuberculosis, and have had results that were suggestive of further trial in these diseases.

Ulcers of the mouth of the womb can be cured by using this mixture—sometimes the pure acid. I have relieved dysmenorrhea a great many times by passing the cotton on holder (saturated with 50 per cent. mixture) through the neck of the uterus—a relief which is very gratifying to the patient.

Robert Mason, M.D.
Exeter, N. H.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ABERDEEN UNIVERSITY, 400TH ANNIVERSARY, ROYAL CEREMONY—ARE CELTS PRONE TO LUNACY?—NOISES FROM A SANITARY ASPECT—POOR-LAW INSTITUTIONS FOR SPECIAL DISEASES—VACCINATION—LONDON UNIVERSITY—OPEN-AIR LEAGUE—THE LATE DR. HENRY TWEEDY.

London, September 28, 1906.

Aberdeen has all this week drawn to itself the chief attention of medical, scientific, and literary circles. The preparations for the celebration of the 400th anniversary of its University have been for some time a familiar theme of surprise or praise, and now the great function, including the opening of the new Marischal College by the King and Queen, which took place yesterday, is matter of history. The foundation dates from 1495, when Pope Alexander VI issued the Bull which resulted a few years later in the establishment of King's College; a century later Marischal College was founded by the fifth earl of that name. The two were only amalgamated in 1860. At present arts and divinity have their home in King's and medicine in Marischal. It is the latter which is the occasion of no small part of the proccedings, for it has been practically rebuilt and is said to be the largest granite structure in the world, the whole of the buildings being of the famous granite of Aberdeen. The tower which dominates all at a height of 235 feet, the gift of Mr. Mitchell, a graduate, is in the Gothic style of the English perpendicular period, the lines of which are finely displayed in the hard granite. I hear that the cost has been from £150,000 to £200,000. Delegates and visitors from all countries, not a few from the United States, have thronged the city all the week and had their share in the rejoicings and entertainments lavishly provided by the University, the city, and the inhabitants. The official commemoration began with service in the University chapel at King's College on Tuesday, and a remarkable procession of delegates in academic robes through the principal streets to the Strathcona Hall, erected by Lord Strathcona for the purpose of accommodating 2,400 guests his lordship has invited to a great banquet, and to serve other parts of the celebrations. Arrived at the hall, every seat—and it holds 4,000—was quickly occupied, and Lord Strathcona, as Chancellor of the University, welcomed the assembly as a world-parliament of universities, animated by a single-minded desire to congratulate the ancient one which had kept the sacred torch of learning burning brightly for four centuries. The presentation of addresses occupied nearly two hours. In the evening a great banquet was given by the Lord Provost and Municipality.

On Wednesday the chief event was the conferring of honorary degrees in Marischal College, presided over by the Chancellor, Lord Strathcona, supported on the right by the principal, Prof. Lang, and on the left by Sir F. Treves as Lord Rector of the year. Eighteen degrees of D.D. were given and 114 of LL.D. Among the latter were naturally representatives of science and medicine. Of these last, Sir F. Laking, physician to the King, who is only just convalescent from a severe illness, received quite an ovation, expressing the sympathy and pleasure of the great audience. Afterwards there was a reception by the University chiefs at King's College of more than 4,000 guests, and athletic sports by the students in the recreation grounds. In the evening a reception in the art gallery and a ball in the music hall by the students. But the great day was yesterday, when the King and Queen went to Aberdeen for the opening ceremony. At the boundary their majesties were received by the municipal authorities. The Lord Provost presented the keys to the King, which were returned with a word or two, a great procession was formed and passed through about two miles of crowded masses of Aberdeenians to Marischal College. Here an address upon the University was read and the King, having replied, declared the new buildings open. Thereupon the University Choral Society struck up a psalm, in the singing of which the King and all the assembly joined. The Dean of the faculty offered prayer, and afterward a great number of presentations to their majesties were made of the staff and others connected with the University.

Then came an unusual but pathetic incident. A poor man on crutches was brought and the King pinned on his breast the Albert medal, warmly shaking his hand. The medal was awarded for a brave attempt to save an old man from a railway train, the recipient, Robert Munro, being crippled in the effort. After inspecting the new building the King and Queen went to the municipal buildings, where

the Lord Provost provided luncheon and was knighted. An address from the corporation was also received. On returning to the station, their majesties were again acclaimed by the population, and at a point near the Prince Consort's statue three hundred veterans of the Crimean and later wars were massed and made their cheers heard.

The Chancellor's great banquet, mentioned above, took place in the evening, and it is declared to have equaled expectations. He also gave £500 to the municipality to feast the poor of the city. The streets were illuminated and there was a grand display of fireworks at the Links. Today the program includes excursions to various places of interest, a reception at the Royal Infirmary of members of the medical profession, an "at home" in Marischal College, and a students' symposium in the music hall. Correspondents say that the north of Scotland has enjoyed magnificent weather all the season, rain falling only once this month, and the tradition of King's weather having been justified yesterday.

Is the Celtic race particularly prone to insanity? An affirmative answer seems to be the conclusion of inspectors in Ireland from an exhaustive report they have presented to the Lord Lieutenant, on the alleged increase of insanity in that country. They state that the statistics of other countries even more than those of Ireland itself point to the fact that it is so, notwithstanding the undoubted intellectual gifts of the race. As to whether insanity is actually or only apparently on the increase, the inspectors say the statistics do not afford information on which a definite conclusion can be based. It is obvious, however, that they lean to the opinion that the great numerical increase, as shown by the census and the statistics of public institutions, represents an apparent rather than an actual increase, for they attribute it largely to the accumulation taking place in public asylums, party to a reduction of population by emigration, partly to the return of emigrants suffering from breakdowns, who have come back voluntarily or been repatriated by the United States, and they remark that the emigration of the strong and healthy, among whom the ratio would have been small, increases that of those left behind and further lowers the standard of mental and bodily health by eliminating many of those best fitted to survive and propagate the race. As to causes, next to heredity (itself sometimes the direct result of alcoholic excess in the progenitor), intemperance continues to head the list. The statistics also show that general paralysis of the insane, at one time almost unknown in Ireland, is increasing in the populous districts. At the same time it is less prevalent than in other countries, and in the rural districts practically nonexistent. This, they think, is perhaps to a large extent due to the high standard of sexual morality which obtains all over Ireland.

Dr. Hyslop of Bridewell and Bethlehem Hospitals read an interesting paper at the recent conference of sanitary inspectors, in which he dealt with "Noise in Its Sanitary Aspect." In some industries, he remarked, excessive noise set up deafness as a protection to the brain tracts. But beyond such cases our brains are fully exposed by night and day to whatever stimulus may fall upon the auditory mechanism, and Londoners know what these stimulants are. Referring to some recent statements respecting the number of hours of sleep needed by different persons and classes, Dr. Hyslop said the actual number of hours of unconsciousness was of little importance, compared to those of brain rest. Those who slept longest were not necessarily the most refreshed. The restorative power of sleep is more due to quality than quantity. Complete insomnia for more than four weeks terminated in mental or even physical death. As to causes, nothing in city life, except worry, was more apt to produce brain unrest and its sequels than the incessant stimulating of the brain through the auditory organs. He would put down many of the noises by stringent legislation. Street cries, horns, whistles, chimes, signals, and so on, were only nuisances night and day. Improved roads, rubber tires, and public control over noisy vehicles, were required, and the restriction of heavy traffic to certain roads and hours, should be enforced. Sir J. Crichton Browne, who presided, remarked that nothing was more distracting than cock-crowing; Carlyle was troubled by it, and a Scotch poet changed his residence on account of it. He had himself been troubled by a bantam of indefatigable habits. There was, however, a story of an old woman who refused to sign a protest against steam sirens, as they reminded her of the last trump.

Mr. Duck, in proposing a vote of thanks, said it would be interesting to learn from Dr. Hyslop the extent to which the motorist, with his goggles, noise, and driving costume, was disturbing the brain centers of the unfortunate passengers on the highways.

The Local Government Board has issued a circular letter to the London Board of Guardians, calling attention to their apparent want of appreciation of the homes and institutions, provided for children chargeable to the Unions who are suffering from eye and other diseases, and in need of special treatment or of sea air. The guardians are also reminded of the necessity of reports by their medical officers as to children in the Unions whom they might recommend for treatment in these institutions.

The annual report of the medical officer of the Local Government Board states that the better observance of the vaccination law, mentioned in last year's report, has been maintained. But the general upward tendency in the matter of infantile vaccination has not been universal. Some counties show a higher percentage of "births vaccinated" than the country as a whole, and some counties remain below. As with counties, so with Poor-Law Unions, the areas directly concerned in vaccination and ministration. Nevertheless, comparing the present and past, there is shown in both areas an advance to a higher grade of acceptance of vaccination.

Sir Edward Buck, Vice-Chancellor of the London University, delivered the inaugural address at the opening session of Birkbeck College, on Wednesday evening. He said there were now 820 teachers in London recognized by the University—a far larger number than those at the Berlin University and Charlottenburg Institute combined. He believed the University of London would become the largest and most influential on the face of the earth.

The Open-Air League, formed early in this year, will open its first sanatorium colony in Essex in the next few weeks, for the accommodation of twenty-five patients, at an average cost of 25 shillings a week.

Dr. Henry Tweedy of Dublin, the father of the profession in Ireland, has died at the age of ninety-six. He retained his vigor of body and mind up to this ripe age. But a few days before death he had a fall and sustained a fracture of the neck of the femur. He leaves his son, Dr. H. C. Tweedy, physician of Stevens' Hospital; Dr. Hastings Tweedy, the Master of the Rotunda, is a nephew. Sir W. Longly is his son-in-law. Dr. Tweedy took the license of the College of Physicians in 1836 and the M.D., Glas., 1838. He always took great interest in all charitable and religious works, and for many years these have been his chief objects. Our venerable colleague carries with him the respect and affection of those who knew him.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

OPENING OF MEDICAL COLLEGES—NEW PROVINCIAL BOARD OF HEALTH FOR ONTARIO—MEDICAL COUNCIL ELECTIONS—MEETING OF THE FRENCH-SPEAKING PHYSICIANS AND SURGEONS AT THREE RIVERS—BRITISH COLUMBIA MEDICAL ASSOCIATION—THE QUESTION OF MILK ADULTERATION.

Toronto, October 13, 1906.

The Canadian medical colleges have opened with a larger attendance of students than usual. The opening address at the medical department of Toronto University was delivered by Sir Almroth E. Wright of St. Mary's Hospital, London, England. His subject was "Inoculation with Bacterial Vaccines." He showed that the human body was continually seeking to ward off the attacks of microbes, and in illustration explained how the microbe responsible for a common boil succeeded in invading the body and how the human system rid itself of its enemy. To cure such a condition we relied upon certain substances in the blood which had been discovered and called opsonins. These acted in conjunction with the white corpuscles to eradicate the infection of microbes. The same theory applied also to all other microbic infections, the chief of them being those due to the tubercle bacillus. In his description of the method by which nature was assisted in getting rid of these microscopic enemies the lecturer dwelt on the value of inoculation with preparations from the very microbe that was originally responsible for the infection. A number of interesting and instructive cases were cited in which a cure had been effected and which would have been considered incurable before this valuable discovery had been made.

The opening at McGill College, Montreal, was a most successful one. Dr. R. F. Ruttan delivered the inaugural address. There were at least three hundred undergraduates present. The address recalled the foundation of McGill Medical College seventy-five years ago, when Drs. Robertson, Holmes, Stevenson, and Caldwell began the systematic teaching of medicine in Montreal. These men were also instrumental in establishing Montreal General Hospital. The history of McGill has ever been one of progress, and the attendance at the opening this year may well be taken as indicating another session of progressive growth. It is

interesting to note that the Department of Dentistry is now identified with the Medical Department, and the dental student is compelled to take the full medical curriculum for two years—afterward devoting the remaining two years to his own specialty. The medical course at McGill is now extended over five years, with special work assigned for each year.

A new Provincial Board of Health for the Province of Ontario has recently been created. The new board consists of Dr. Charles Sheard of Toronto, Dr. M. I. Beeman of Newburgh, Dr. W. J. Robinson of Guelph, Dr. W. R. Hall of Chatham, Dr. C. B. Coughlin of Peterboro, and Dr. J. W. S. McCullough of Alliston. There is great satisfaction expressed with the appointments which have been made, and the new board will find many interesting problems to engage their attention.

This is the year for the election of territorial representatives to the Medical Council of Ontario. These elections are held every four years, when seventeen representatives are elected from different portions of Ontario. Each medical practitioner has a vote in the division in which he is a resident, and the member to be elected must also be a resident of the division. Besides the territorial representatives there are eight collegiate representatives appointed by the boards of the different universities and colleges. There are also five homeopathic representatives in the Medical Council who are elected by the homeopathic practitioners in Ontario. The provision for homeopathic representatives was made thirty years ago, when the Ontario Medical Act was first introduced. There is no homeopathic College in Canada, and there are less than fifty homeopathic physicians left; yet, strange to say, these fifty have five representatives in the Medical Council, while over three thousand regular practitioners in Ontario elect only seventeen representatives.

The French-speaking members of the medical profession in Canada have a live medical organization, "L'Association des Médecins de Langue Française de l'Amerique du Nord," which has had a successful meeting at Three Rivers, Quebec. The subjects under discussion were tuberculosis, alcoholism, and the hygiene of infants. Upon these subjects several interesting and valuable papers have been read. The majority of the local French medical societies of Canada and the United States were represented by delegates and several of the societies in France also sent well-known men as representatives. The Therapeutic Society of Paris sent Dr. Triboulet on purpose to represent the views of that society in regard to alcoholism. M. Proust represented the Medical Faculty of Paris and M. Lori, Professor of Hygiene in the Higher School of Colonial Agriculture, represented the French Association for the Advancement of Science. The officers elected to arrange for the next meeting were: *President,* Dr. A. Simard; *Vice-Presidents,* Dr. Hervieux, Dr. Lanoix, and Dr. Sirois; *Secretary,* Dr. Paquette; and *Treasurer,* Dr. Doriow. The next meeting will probably be held in Quebec City.

The annual meeting of the British Columbia Medical Association was held this year at New Westminster, and was, in point of attendance, and interesting program, the best yet held in the Western province. The president, Dr. George Drew, in his annual address touched upon many interesting historical reminiscences in connection with medical progress in the West, and made an eloquent plea for firm adherence to duty, principle, and honor upon questions of moral and professional character, as all-important in fostering and developing the best interests of the profession. The meeting was made most interesting by the discussions, that were a feature of the session. The officers for the coming year are: *President,* Dr. R. L. Fraser, Victoria; *Vice-President,* Dr. J. M. Pearson, Vancouver; *Secretary,* Dr. R. Eden Walker, New Westminster; *Treasurer,* Dr. J. D. Helmcken, Victoria. The next meeting of the association will be held at Victoria.

A bulletin, recently issued by the Chemical Department of the Inland Revenue Department, has called attention to the important subject of milk adulteration. Of 31 samples of milk collected in Toronto 13 were found genuine, 11 doubtful, and 7 adulterated. Regular inspection of dairies by health officers and frequent analyses are strongly advocated and will probably form one of the first questions to be discussed by the new Provincial Board of Health. Montreal has now a pure milk league. During the discussion on milk supplies in the Section of State Medicine at the recent meeting of the British Medical Association at Toronto Professor Glaister of Glasgow urged that the weak spot in the existing law and regulations respecting the milk supplies was that executive action was deferred until the harm was done. He advocated a system of inspection and supervision which would be, as far as possible, preventive in its operation. Where milk is collected for distribution and use in large centers, especially in cities, the collection of it, as well as the surroundings from which it is derived, should positively be under the local Board of Health most concerned.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

MEDICAL VISITORS FROM FRANCE—THE TUBERCULOSIS CAMPAIGN—THE PHYSIOLOGY OF HEARING—THE KAISERIN FRIEDRICH-HAUS.

BERLIN, September 30, 1906.

THE physicians of Berlin, from August 16 to 19, gave themselves up entirely to the pleasant task of showing their French guests the medical institutions and other attractions of our capital. The committee of arrangements, of which our prominent gynecologist Kossmann was the president, carried out all the details of entertainment in most successful manner. It was no light task for the strangers to visit within three days such great institutions as the Königliche Klinik, Königliche Charité, Garnisonlazarett Tempelhof, Rudolf Virchow Krankenhaus, Am Urban, Institut für Infektionskrankheiten, Heilanstalt in Beeliz, and several private hospitals, in addition to the Langenbeck Haus and the Kaiserin Friedrich-Haus, to say nothing of the receptions and other social entertainments. This was the first time that a body of French physicians of this size, the deputation numbering about forty, had visited our country, and doubtless one of the speakers who delivered an address was right in saying that science knows no political enmity, though I believe that such meetings are not only of scientific but also of political benefit. The interesting proposal was made by Kutner of founding an international committee for organizing international medical journeys for purposes of study. The committee was promptly formed and has as its president Kossmann of Berlin, and as members, Bazot of Paris, Guyot of Geneva, Kutner of Berlin, Lifrange-Bertrix of Belgium, and Tini of Bologna.

An interesting summary of the work of the Berliner Auskunfts und Füsorgestellen für Tuberkulose has been presented by Dr. Kaiserling, the general secretary of the organization. In the period of nineteen months 15,646 patients were examined, about 3,000 being males, 5,500 females, and 6,000 children. Whenever possible the entire family of the patient was examined and the total number of examinations made exceeds 50,000. Kaiserling believes that school children suffer from tuberculosis to a greater degree than has hitherto been supposed, and that the disease becomes manifest when young adults begin to do more arduous work. Over a thousand persons were admitted to sanatoria and just as many to convalescent homes, and in many instances families deprived in this way of the bread-winner were cared for by the organization. The eleven official nurses made 18,540 visits for the purpose of teaching sanitary rules, and to improve the home conditions of the poor.

At the session of the Physiologische Geschellshaft held in the middle of the summer Kalischer presented a striking demonstration which seems likely to throw additional light on the physiology of hearing. Dogs were trained to pick up pieces of meat when certain tones were sounded on the piano or organ and to leave the food untouched when other tones were played. The accuracy of the performance of the animals was not interfered with by extirpating the auditory center, and also the cochlea of the one side, but the experiment failed if both cochleæ were removed. It appeared that dogs possess an extraordinary tone sense and are able to distinguish a single tone in a chord.

During the leisure of the summer there have been many opportunities for inspecting the Kaiserin Friedrich-Haus, the dedication ceremonies of which I described in a previous letter. The magnificent building situated in the neighborhood of the Charité Hospital is intended to furnish physicians with a central meeting place in which they can acquaint themselves with the progress that is being made in all branches of medical science, and complete outfits are provided which can be sent for teaching purposes to any part of the Empire in which they may be desired. In the third story of the building are a number of laboratories equipped for chemical and microscopical investigations, the equipment being unusually complete. Another part of the building is intended to serve for bacteriological and experimental studies, a special laboratory being reserved for work involving the handling of dangerous cultures. The Roentgen-ray outfit and the equipment for medical photoggraphy is the finest yet installed in Berlin, and it is expected that the building will become a center for the production of medical photographs. An interesting feature is the laboratory devoted to the purpose of making plaster casts of skin diseases, etc., of which a great collection has already been formed. The chief attraction of the whole building is the beautiful auditorium, constructed in amphi-

theater fashion and provided with a specially designed blackboard which by a simple mechanism can be lowered so as to uncover a screen for use with the projection apparatus. All the facilities of the building may be made use of for teaching or research by any physician who can provide proofs of his ability. It is intended, furthermore, to have the Kaiserin Friederich-Haus the center for the whole post-graduate medical life of Germany. Teaching appliances of every kind have been assembled in collections so packed as to be readily transportable, and these can easily be shipped to any point where it is desired to give one or more lectures. Other features of the building are a valuable collection of exhibits relating to the history of medicine, and to various systems of treatment, such as medico-mechanical apparatus, physical dietetic methods, and medical electricity and optics. The well-known watering places such as Carlsbad, Ems, Franzensbad, Wildungen, etc., have arranged exhibitions intended to illustrate the characteristics of their springs and institutions. Finally, the reading-room must be mentioned, which has been lavishly provided with books and periodicals by the great medical journals.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 4, 1906.

The Ulnar Nerve as a Landmark of the Elbow.—F. J. Cotton regards this nerve as an indisputable landmark. It lies in an anatomically constant position behind the internal epicondyle, bound down loosely by fibrous tissue; it is a large nerve; it is covered by no muscle; it can readily be reached even in the presence of much swelling, if this swelling is slowly massaged away; it may be identified in every case if reached, not only because it is the only cordlike structure at the back of the elbow that can be rolled under the finger, but also because the patient can readily assist in its identification just as he can contribute to the identification of kidney or testis, by the subjective sensation; no one is in the slightest doubt as to when his "funny bone" is touched, whether there be an injury in this region or not. In many cases no other landmark at the elbow can be relied on; either condyle may be displaced by fracture and lose its characteristic shape and place so far that it cannot certainly be identified. Particularly in the common and often overlooked fractures (or, more properly, epiphyseal separations) of the internal epicondyle, it is of obvious service. If we can feel an ulnar nerve not lying in the backward hollow of the hook of the epicondyle, but lying exposed near the tip of a flat surface of bone, no argument is needed. The epicondyle is gone and we shall eventually find it displaced forward and downward as usual. The objection may be raised, and fairly raised, that the ulnar nerve may be displaced. The author has observed a good many cases with regard to this displacement and has reported certain cases of the recurrent displacement; but this recurrent displacement is relatively uncommon, and pertains only to the flexed position; it is present only in cases in which the nerve is *obviously* movable beyond normal.

New York Medical Journal, October 6, 1906.

Peculiar Attitudes in Epilepsy During Sleep.—N. B. Ross records some interesting observations made at the Craig Colony. He has observed a peculiar similarity of posture during sleep among low-grade patients. Many of them are curled up—that is, the legs are flexed on the thighs, while the arms are in a semi-flexed position back of the knees when the latter are flexed. The head is bent forward until it rests on the knees, and often this grade of patients entirely cover their heads with blankets, exposing them to the danger of asphyxia in attacks during sleep. Others of this grade sleep in a sitting posture night after night the year round; others simply brace the head against the pillow as it stands on edge at the head of the bed, while still others sleep with their arms above their heads with the fingers clasped, thus supporting the head. Some sleep with their heads resting upon elbows and hands, while others sleep in a posture in which the head is flexed until it touches the breast, without giving any support whatever to the head. A few lay outstretched upon the back with heads greatly extended, doing so by means of a pillow rolled up and arranged to conform to the scapular and interscapular region of the back. A great number of these patients prefer to sleep curled up on a mattress upon the floor, for the reason that they fear attacks during the night. They would rather thus sleep than occupy a bed of ordinary height, from which they might fall. Some excellent photographs illustrate the paper.

The Relation of Gastric Ulcer to Gastric Cancer.—M. R. Barker relates the case of a man of thirty-seven years in whom all the symptoms pointed unmistakably to peptic ulcer. Under a long-continued treatment he improved, when the hydrochloric acid in the gastric secretion began steadily to diminish. Gradually there developed all the symptoms of gastric cancer, which was confirmed by autopsy, a large open ulcer being found in the pylorus, the edges of which were elevated and infiltrated with cancer cells. The author believes that in such ulcer cases the acid diminution points unmistakably toward malignant invasion and should be regarded with the gravest suspicion, although the patient seems to be doing well. This cancerous invasion may occur in an open ulcer or in the scar tissue left by a preceding healed ulcer. Trauma of some kind may be the initial factor leading to the malignant invasion. The morbific cancer agent, whatever it may be, may enter the tissues at the time of injury and remain dormant for a long time. When an ulcerating area is thus infected it never heals, though the outbreaking evidences of malignancy may be long deferred. In regard to the disappearance of the acid, the author ventures the suggestion that in the evolution of the malignant process, a toxin is produced which, acting upon the nerve centers which control the gastric cells, paralyzes them, thus rendering these cells inactive, and that this toxin is produced as quickly as the cancer invades the tissues, and increases as the cancer increases, and as the toxin increases the hydrochloric acid decreases, until it has totally disappeared.

Journal of the American Medical Association, October 13, 1906.

Hemorrhage in the Newborn.—H. McClanahan reports six cases of hemorrhage occurring spontaneously in the newborn, with histories; several cases of traumatic hemorrhage are also briefly reported. One of the spontaneous cases was a fatal hemorrhage from the lungs, which apparently is rather rare. He gives the principal facts in regard to hemorrhage of the newborn, its occurrence within the first few days after birth, its serious character in most forms, its apparent lack of any relation to hemophilia, and the obscurity of its etiology. He thinks that it is probably due to some unknown specific cause producing a change in the blood-vessels. In hemorrhages occurring later than the first ten days of life, he considers septic infection as the most likely factor. His experience, apparently, does not afford any special support to the theory of hereditary syphilis in these cases, though it is considered an important predisposing cause.

Benign Cystic Epithelioma.—J. V. Shoemaker and L. Napoleon Boston report a case of this comparatively rare condition, of which they have been able to find records of twenty-four other cases in the literature. The growths occupied the right arm; the general condition was that of moderate secondary anemia, which improved under treatment. Microscopic examination made it evident that the neoplasms originated in the hair follicles and were examples of what has been described as trichoepithelioma. Few cysts were present owing to the slight age of the tumors, they having existed but a few months. These benign tumors of the skin, the authors remark, have received but little attention from pathologists.

Banti's Disease.—W. L. Bierring and E. Egdahl report a case of Banti's disease in which splenectomy was performed and discuss the blood findings. The notable facts are summarized as follows: 1. Before the operation the blood condition was that of the secondary type of anemia, low percentage of hemoglobin and leucopenia. 2. After splenectomy there was a slight fall in red cells, then a rise, a leucocytosis at its maximum twelve days after the operation and characterized by a relative increase in the mononuclear leucocytes, especially the large mononuclears. 3. The absence of myelocytes and the scarcity of nucleated reds, both before and after splenectomy. Discussing these findings in connection with those of others in this disease, the authors remark as to the significance of these blood changes, in hypertrophy of the spleen from any cause, that a decrease in hemoglobin, in erythrocytes, and in many cases also in the white corpuscles, is very likely to follow. How this leucopenia occurs is hard to explain with our present ideas of the hematopoetic function of the spleen, while the cause of the general secondary anemia with splenic hyperplasia is as yet hypothetical. The good results from splenectomy in both splenic anemia and Banti's disease seem to favor the view that the spleen is in some way responsible for the poor blood conditions. The lymphocytosis after splenectomy must be regarded as an effort at compensation. The authors

conclude that in considering the blood findings in the two diseases, Banti's disease and splenic anemia, before and after splenectomy, one is led to the opinion that, whatever the nature of the disease process or the causative influence, the blood-forming organs are not particularly concerned. The more likely points of attack are the vascular channels, the tissues of the spleen, and in time also those of the liver.

The Open-Air Treatment of Pneumonia.—W. P. Northrup for over eleven years has been using free ventilation and fresh air treatment in pneumonia. The patients most favorably affected by open-air treatment are those with severe poisoning, with delirium, partial cyanosis, or deep stupor. In Northrup's experience all patients do better in cool fresh air, which can be secured in private practise by screening off a portion of a room by an open window. None have been harmed, in his observation, and some have been greatly benefited and possibly saved by the cold fresh-air treatment. If pneumonia, due to an infecting agent, is thus benefited, the value of the treatment for other infectious diseases is suggested, and, in fact, he has tried it in many others, including typhoid fever with severe bronchitis, whooping-cough with bronchitis and convulsions, with excellent results. He considers it, in fact, the ideal treatment for septic fevers. The only regulation is to keep the patient comfortable and especially to keep the feet warm.

Gangosa.—O. J. Mink and N. T. McLean describe the disease known as gangosa, a form of ulcerated rhinopharyngitis which seems to be endemic in the Ladrone and Caroline Islands, but has been reported also from some other tropical regions. It has evidently existed there for at least 150 years, is confined to the natives, and does not seem to be hereditary or due to diet. The evidence is also against its being a luetic manifestation or a sequel to yaws. The authors' opinion is that it is due to some specific infection, possibly carried by flies or by direct contact, overcrowding, etc. The disease seldom being fatal, few chances for autopsy occur, and other than local symptoms and lesions have not been observed. Fordyce says that the lesion is a granuloma of undetermined nature, the histological picture somewhat resembling tuberculosis. It commences with an ulceration of the pharyngeal mucosa, becoming rapidly progressive and involving sometimes the hard palate, nose, eyes, and face. The tongue and muscles of deglutition are spared, and hearing is rarely affected. In the quiescent stage, scar tissue remains, but the active stage may continue indefinitely or may be arrested at any time. A fulminating type occurs in young children, usually proving fatal in forty-eight hours and closely resembling diphtheria. If the patient survives beyond that period the disease follows the usual course. The diagnosis is simple. The sudden onset distinguishes it from lepra and lupus, and the characteristic bacteria are absent. The symptoms differ from syphilis and specific treatment is a failure. The fulminating type is diagnosed from diphtheria by the absence of the Klebs-Loeffler bacillus and the characteristic mutilation. The contagiousness of the disease is evident, and isolation, which was discontinued at the time of the American occupation, has again been made compulsory. In the fulminating type rigid quarantine should be enforced. In the early stages treatment clearly limits the progress of the disease. It is essentially local and aims to destroy the affected area. Tincture of iodin, employed freely, is apparently the best agent, though in some cases the actual cautery may be more effective. Antiseptic mouth washes should also be used and tonic treatment when necessary. As a deodorant, potassium permanganate, 1 per cent. solution, has proved most advantageous. The authors suggest the possible utility of *x*-ray or light treatment. In the fulminating type the treatment should be symptomatic, combined with thorough local disinfection.

The Bacteria in Scarlatinal and Normal Throats.—From a study of 154 throat cultures, 51 from normal throats, 75 from cases of scarlatina, 14 of measles, 5 of tonsillitis, 5 of pneumonia, and 4 of pharyngitis, G. F. Ruediger sums up his findings as follows: *Streptococcus pyogenes* is constantly and abundantly found on the tonsils in cases of tonsillitis and scarlatina before the subsidence of the inflammation in the throat. The organisms rapidly decrease in numbers after subsidence of the throat inflammation. *Streptococcus pyogenes* cannot be considered a normal resident of all healthy throats, though it was found in small numbers in 60 per cent. of the cases examined. Pneumococci of low virulence were found in 64 out of 71 throats. A large group of organisms lying between the typical *Streptococcus pyogenes* and pneumococcus were found in all normal throats and in nearly all diseased throats. They have very little virulence for rabbits, and as they are found in nearly all cases they may be considered as normal inhabitants of the throat. *Streptococcus pyogenes* from normal throats appears to have a slightly greater virulence than these organisms from scarlatinal throats.

The Lancet, September 29, 1906.

Arterial Blood Pressure in Heart Disease.—H. J. Starling details the results of personal experiments and observations. He considers it of great importance to note this condition of pressure in all cases of failing heart. It enables us to classify a given case under one of two headings. In the first the heart muscle is at fault. If we bleed, it is to relieve temporarily the distended right heart. If we give oxygen, it is to improve the nutrition of the heart and to relieve it in cases of maloxygenation by relaxation of arterial pressure. In the second instance we should reduce the high pressure, which has worn down the working power of the heart muscle. Bleeding in such cases would not alone give temporary relief to the heart. It would also, by affording a stimulus to building up of the tissue, enable the organism to apply its nitrogenous waste products to this purpose, and so tend to the purification of the circulating fluid. On the assumption that there is a plethora in the widest sense of the term, and that it is primarily due to an excess of income over expenditure, the treatment which would seem to be indicated would run on the old-fashioned lines of bleeding and purging. At the same time there must be a complete reformation of mode of life. The income must be diminished by limitation of food; the output must be increased where necessary by regulated exercise. It is probably in cases such as these that Oertel's methods of treatment of heart disease have been most successful. Whether, however, limitation of fluids in the diet is desirable, the author is inclined to doubt. Although increased fluids tend to the perpetuation of the plethora present in these cases, too rigid a restriction of fluid must seriously hinder the excretion of the hypothetic toxic substances which we have assumed to be the cause of the disorder.

Endemic Hematuria.—P. G. Stock gives some notes on sixty-five cases of endemic hematuria, occurring among the soldiers in the late South African war. These observations seem to show that the average incubation period of the disease is about six weeks. Concerning treatment, the author is inclined to think that the best results have followed the administration of methylene blue. It has been suggested that the use of a toxin in such cases should produce good results, and this is borne out by the following facts: Two patients who were suffering from bilharzia contracted enteric fever and on convalescing the urine was found to be free from the ova, and during the time they were under observation (some months) they had no recurrence of symptoms. At the post-mortem examination which was held on a native who died from dysentery and in which the bilharzia parasites were dissected out within two hours of death, the worms were found to be dead; there were well-marked dysenteric lesions of the intestines. The ascaris lumbricoides is almost invariably killed by acute infections. This seems to offer some hope of success in what must be either an incurable disease or one in which time is the only remedy. The toxin might be conveniently administered by the hypodermic injection of Wright's antityphoid serum. It would not be necessary to give sufficiently large doses to produce a serum reaction, but a series of small doses might be tried which would cause little or no inconvenience. The author notes the general opinion that there is no danger of patients spreading the disease, but admits that no positive opinion can be given on this point until more is known of certain phases in the life history of the bilharzia.

A Case of Plague.—This study is made by J. B. Cleland. The points brought out may be expressed in the following statements: Living plague bacilli exert only a mechanical effect and not a toxic one on the tissues, and as they only rarely remain and multiply at the seat of inoculation, there is seldom any local reaction and as rarely a lymphangitis. The glands of the groin are those draining the area of inoculation. In them the bacilli are first arrested, and greatly multiply before passing on to other glands or to the blood stream. Hence we have an intense local reaction, *i.e.*, the bubo. These are sometimes wanting, because the bacilli may have entered the body through other routes than the skin, or if the latter has occurred they may have escaped the nearest glands by entering more directly into the blood stream, or may have multiplied in the glands to a less extent than usual. Symptoms do not appear during the incubation period because the living bacilli are not toxic and some days must elapse before antimicrobic bodies or other forces can destroy a sufficient number of the bacilli and so set free large doses of toxin.

British Medical Journal, September 29, 1906.

Tuberculous Cervical Adenitis.—A Gregor reports the case of a child of six years with a swelling on the left side of the neck, of one week's duration. There was a distinct family history of tuberculosis on the father's side. The gland was tender and painful, and in a few days sup-

purated. The abscess was opened and drained. The discharge continued ten days and the whole gland began to break down. The parents refused a general curetting of the cavity under anesthesia. It was finally subjected to irradiation, fifteen sittings being held, each lasting fifteen minutes. No violent reaction followed, but the granulating surface closed up and healing was finally complete.

Remarks Upon the Pneumotoxin.—A. Macfayden details the results of certain animal experimentation. He finds it possible to extract an acutely lethal toxin from the bodies of virulent pneumococci, and one of much greater potency than the soluble toxins described by previous writers. The endotoxin of the pneumococcus is sensitive to the action of heat. A filtered cell juice heated to 55° C. for an hour failed to kill in doses of 0.5 and 1 c.c., while 2 c.c. only caused death at the end of five days. The unheated juice was acutely lethal in doses of 1-20 c.c. The prolonged action of chloroform vapor is also injurious to the toxin. After an exposure of one hour to chloroform vapor, 0.5, 1, and 2 c.c. did not kill the test animals, the lethal dose of the untreated toxic cell juice being 1-20 c.c. References are made to the work of other observers.

Cerebral and Ophthalmic Complications in Sphenoidal Sinusitis.—St. Clair Thompson makes a careful and elaborate study of this question, and reports two cases in which the sphenoidal origin of intracranial suppuration was confirmed by autopsy. He has made a careful search for previously recorded cases and has been able to bring together 40 cases, which are carefully analyzed. In 17, meningitis was the only or predominant symptom; in 4, thrombosis of the cavernous sinus; in 13, thrombosis and basic meningitis; in 2, meningeal septicemia. Encysted dural abscess, hemorrhagic encephalitis, intracranial abscess, phlebitis of the cavernous sinus, intracranial hemorrhage, and suppurative encephalitis were found respectively once. The symptoms of sphenoidal sinusitis are classified according to their effects on neighboring and distant organs and on the general health. Various affections are simulated by cerebral infection from this source. Thus patients thus affected were admitted to hospital for phlegmon of cheek, ear disease, croupous pneumonia, tuberculous meningitis, tonsillitis, typhoid fever, etc., but in each instance the progress and termination of the case showed cerebral infection from the sphenoidal sinus. The route of infection may be from the sinus mucosa, then to the subarachnoid space by direct transference through bone, by the veins, or by the lymphatics. Various bacteria have been isolated from these cases, streptococci, staphylococci, pneumococci, etc. It is quite possible that the sinus itself becomes originally infected through the tonsil. A series of cases is referred to, bearing out this theory. The nearness of the sinus to the orbit would naturally lead to prominent eye symptoms. In one of the author's two personal cases, proptosis and chemosis were present and due to a retro-ocular abscess. Edema of the eyelids, coincident with a nasal discharge, should always make us suspicious of deep-seated trouble. The nasal discharge is not always in evidence. Its absence has been noted in several cases. The outpouring of pus from the sinus may be intermittent, and it is often very difficult to wash out this sinus without a preliminary operation on the middle turbinate. Several diagrams illustrate the anatomical points of the paper, which is an able contribution on a most important topic. A full bibliography is appended.

Berliner klinische Wochenschrift, September 24, 1906.

The Treatment of Postoperative Sinuses by Wright's Vaccine Method.—Weinstein employed a method founded on Wright's researches on opsonins for the treatment of obstinate sinuses following laparotomies. In each instance cultures were made from the sinus, and the vaccine prepared from these according to Wright's directions. Great stress is laid on the fact that the organisms used in producing the vaccine must be those that are found in the wound of the particular patient. Four cases were treated, and in two of them the sinus was caused to heal completely, after having persisted for four years in one instance. The third sinus was almost completely closed at the time of writing, but the fourth, which communicated with the intestime and was the result of an operation for appendicitis in which the appendix was not removed, still remains open, though the general character of the wound and of the discharge has improved.

Clinical and Experimental Observations on Gastroptosis.—Rosenberg reports on observations made to determine the correctness of Loening's recent statement that in nearly all cases of gastroptosis the motility is increased. Rosenberg examined twenty cases of this sort and found hypomotility in 70 per cent., hypermotility in 20 per cent., and normal motility in 10 per cent. He believes that in the earlier stages of ptosis there may be a period of temporary hypertrophy of the gastric musculature just as is the case with the development of cardiac dilatation, owing to the increased resistance to be overcome. Later on dilatation takes place, the muscle weakens, and hypomotility results. He suggests that Loening's results were gained from a study of patients still in the stage of hypertrophy.

Muenchener medicinische Wochenschrift, September 25, 1906.

The Transplantation of Human Ovaries.—Cramer reviews the history of attempts in this direction, as well as the theoretical considerations underlying them. He has performed the operation in two cases, in each instance using for the purpose ovaries removed from patients with osteomalacia with the object of curing this condition. In each case the laparotomies were done simultaneously on the patient who was to furnish the ovarian tissue and on the one who was to receive it. In the one case the attempt was made in order to secure the possibility of childbearing for a young woman suffering from atrophy of the uterus and ovaries. The other patient was the victim of a very stormy artificial menopause, resulting from a panhysterectomy. All the patients recovered from the operations without complication and the woman with the atrophic pelvic organs some months later had what apparently was a miscarriage. Preceding this the breasts had become swollen and colostrum could be expressed. In the second case the implanted tissue apparently underwent absorption with considerable promptness, for ten weeks after the operation no trace of it could be detected by bimanual examination.

Pernicious Anemia and Leukemia.—Kelling has already published his opinion that malignant tumors are the result of the implantation in the body tissues of embryonal cells derived from animals in various articles of food, such as raw eggs and uncooked sausage, which latter frequently contains as one of its components uteri of the slaughter animals. He now endeavors to explain the etiology of the malignant blood diseases in similar fashion, and describes several cases of pernicious anemia and leukemia in which he was able to demonstrate in the blood serum of the patients specific precipitin and hemolytic reactions for animal tissues, such as sheep and fowl. He was also able to produce artificial pernicious anemia in a dog by injecting embryonal fowl cells into it, and he found that the animal's bone marrow gave the specific reactions with fowl serum. It is Kelling's opinion that the proliferation of the blood-forming organs which is observed in these diseases is in reality the result of the growth of the foreign cells which have become engrafted in the body. He seeks to explain the nature of pseudoleukemia in a similar way, though he has yet no experimental evidence to justify this view.

Chloroma of the Skull.—Pfeiffer describes a case of this affection occurring in a boy of four years. The first symptoms noted apparently pointed toward an otitic affection, but were soon followed by the development of marked bilateral exophthalmos, severe anemia, enlargement of the cervical lymph glands, marasmus, and death. At the autopsy the typical green tumors were found in the retrobulbar tissues, dura, mastoid process, vertebral column, sternum, and some of the internal organs. The author considers that the following may be regarded as typical symptoms of this unusual condition: Painful exophthalmos, followed by atrophy of the optic nerve, otitic symptoms accompanied by swelling in the temporal region, either on one or both sides, anemia or acute lymphatic leukemia, with glandular enlargements and subcutaneous or submucous hemorrhages, and, finally, the rapid course of the disease and the youth of the patients.

Deutsche medizinische Wochenschrift, September 27, 1906.

Testing the Functional Efficiency of Arteries.—Müller describes a method by means of which it is possible to gain some insight into the functional efficiency of any given individual's arterial system. The underlying principle consists in measuring with the plethysmograph the extent of vascular dilatation or contraction caused by the application of thermic stimuli to the forearm. In the one case a block of ice of a certain size is applied to the bend of the elbow for a certain length of time, and in the other warm water is allowed to circulate through several spiral turns of rubber tubing applied in the same situation. The amplitude of the plethysmographic curve obtained under these conditions affords a means of estimating the functional capacity of the individual's arterial system. As the result of his studies Müller concludes that the functional capacity of an artery in general may be said to be greater the softer and less easily palpable its wall is. In proportion as the wall is thickened the capacity of the artery diminishes, and in the most extreme cases of rigidity the functional efficiency is almost entirely absent. In some cases, however, considerably thickened arteries may yet present normal or even more than normal efficiency.

The Effect of Cholin on Pregnancy.—Werner and Lichtenberg describe a series of experiments made on rabbits by injecting cholin during pregnancy. It was found that by injecting 10 c.c. of a 5 per cent. watery solution of this substance five times at intervals of four days into a pregnant animal, abortion was produced, and on examining the uterus portions of several atrophic and misshapen embryos were found. The daily injection of small amounts of 0.5 per cent. solution caused animals that had previously been fertile either to become entirely sterile or to become much less fruitful. The authors point out the similarity in effect of these cholin injections to the action of the *x*-rays in restricting fertility.

The Methods of Treating Bladder Wounds After Cystotomy.—Baratynski reviews his own experience and that of others in the closure of bladder wounds. The average time of healing in cases in which primary union occurs is 11.5 days; in cases in which most of the wound heals by first intention but there is slight leakage of urine, the average period of healing is 20.3 days. If the condition of the wound requires sutures to be removed, the period is lengthened to 30.5 days, and if the incision is allowed to heal by second intention 66.6 days are required. The author concludes that in cases in which the urine is normal and the vesical mucosa is unaltered, the wound should be sutured completely. The same thing may be done in cases in which the urine does not show marked changes, being neutral or faintly alkaline and there is slight cystitis, under the condition that the latter will be subjected to active treatment. The open treatment of the bladder wound is necessary if there is pronounced cystitis and the urine is alkaline.

The American Journal of the Medical Sciences, September, 1906.

Toxemic Vomiting of Pregnancy.—J. Whitridge Williams states that present evidence seems to justify the classification of serious cases of vomiting during pregnancy as reflex, neurotic, or toxemic, according to the etiological factors concerned. He considers toxemic vomiting a very serious disease. It is a manifestation of a profound disturbance of metabolism. Its exact origin is not known. This affection usually ends in death. In the last stages of the disease the matter vomited has a coffe-ground appearance. No apparent effort is noted during its expulsion. The urine, though diminished in amount, does not contain albumin or casts until shortly before death. It may also apparently show a normal amount of urea as determined by the Doremus method. There is a greatly increased percentage of nitrogen eliminated as ammonia in the early stages, although the nitrogen excreted as urea is decreased. The proportion of amidoacids is increased. The acetone content is very large in some cases. The writer thinks that if the ammonia coefficient exceeds 10 per cent. the diagnosis of toxemic vomiting should be made and the pregnancy at once terminated. Unexpected lesions are found at autopsy. The writer believes that the only way in which advancement in knowledge in this subject may be hoped for is by grouping the cases together according to their anatomical and chemical characteristics and by waiting for the revelation of the significance of the conditions about which little or nothing is now known.

Elephantiasis Non-Parasitica, Secondary to Chronic Cardiac Disease, and Repeated Edema of Pregnancy.—T. W. Hastings describes a case of this nature. The etiological factors he considers a chronic cardiac condition and some local lymphatic deficiency in the right leg. The right leg from the knee down was greatly enlarged. The left leg showed a moderate edema. There was entire freedom from attacks of inflammation in or repeated injuries to the right leg, suggesting that the local condition depends upon some defect in the lymphatics of the affected part. Whether this was congenital or acquired it is difficult to prove. There was persistence without steady increase in size of an edematous condition of the left leg which more strongly suggested some local lymph-vessel deficiency in the right leg. Edema had repeatedly occurred during four pregnancies, and this with the cardiac disease with several periods of broken compensation, would account for the edema in the legs; but it would not account for the thick elephantiatic condition of the skin of the right leg. The patient was born in New Jersey and has never been outside of New York, Pennsylvania, New Jersey, and Illinois. She follows the occupation of silk winder. There is a constant discharge of serous fluid from the right leg. Tissue for histological study has not been obtained. There is no history or evidence of infection. The patient has been treated by bandages, rest, elevation of the leg, and massage. The cardiac condition has also received attention.

Results of the Biterminal Transplantation of Veins.—Alexis Carrel and C. C. Guthrie from their studies have learned that after the transplantation of a segment of vein between the two cut ends of an artery the wall of the artery is only slightly altered, as revealed by the microscope; the wall of the vein becomes enormously thickened, the muscular and fibrous layers of the middle coat and the inner layer of the outer coat being principally involved; there is no evidence of weakening or breaking down of the wall; the ligatures which have been used are enveloped in a dense coat of fibrous tissue. The writers conclude that a venous segment interposed between the cut ends of an artery quickly undergoes anatomical changes; from macroscopic and microscopic standpoints the vein has a strong tendency to assume the character of an artery; from a physiological standpoint it performs the arterial functions.

The Value of Massive Doses of the Salicylates in the Diagnosis and Treatment of Acute Articular Rheumatism.—Thomas Wood Clarke presents the following conclusions: Sodium salicylate can and should be given in much larger doses than are generally used. Given in massive doses it reduces the fever, relieves the pain and swelling, and shortens the course of the disease. It is not injurious to the heart and appears, by quickly cutting off the disease, to offer some protection to that organ. The patient's tolerance to the drug and the rapid cessation of symptoms form valuable therapeutic tests for the diagnosis of acute articular rheumatism.

Infections of the Biliary Tract, with Special Reference to Latent (or Masked) and Typhoid Infections.—A. O. J. Kelly enumerates the following pathways whereby the biliary tract may become infected: The diverticulum of Vater and the common bile duct; the portal circulation; the systemic circulation; the lymphatic circulation and the pathway directly through the wall of the gall-bladder or the gall-ducts from the peritoneum. Doubtless these pathways vary with the infecting agent. Authorities now generally agree that the typhoid bacillus is regularly present in the gall-bladder, and commonly in pure culture, in practically all cases of typhoid fever, this being the one region of the body from which a pure culture of the organism is most likely to be obtained; the typhoid bacillus may persist in the gall-bladder, as well as within gallstones, weeks, months, and even years after the patient has recovered from an attack of typhoid fever; cholangitis and cholecystitis (catarrhal, suppurative, and gangrenous) are by no means infrequent complications of typhoid fever; a history of antecedent typhoid fever may be obtained in many cholelithitic and cholecystitic subjects. The typhoid bacillus may be present in the gall-bladder without exciting pathological lesions, in some cases. There exist also a primary typhoid cholecystitis and cholangitis, an infection of the biliary tract without other evidence of past or present typhoid infection. This affection has not yet been sufficiently studied. The writer cites the history of a number of cases. He declares that it would be wise in all cases of jaundice to undertake bacteriological studies of the blood and the feces. The Gruber-Widal reaction with the typhoid, paratyphoid, and other bacilli should not be neglected.

Branchiogenous Remains and the New Formations to which they Give Rise.—G. Mioni tells us that tumors derived from the remains of the branchial arches have their origin in epithelial germs included at the time of the obliteration of the *sinus cervicalis*, or to the remains of the second branchial arch left after the formation of the pharyngeal segment. They are not truly congenital, since they may begin to develop only after birth, as a result of some sort of stimulant to their growth. They may be divided into three classes: first, those tumors covered with a simple epithelial covering and containing products of the same epithelium. This epithelium may be ciliated or cylindrical, and the contents be mucous, or epidermoid, or both forms combined. The second class consists of remains of the branchial arches, and may be due to inflammations or mechanical disturbances of the walls, becoming adenomatous, carcinomatous, etc. The third class includes teratomata. The commonest form is that of cysts, with walls covered with some form of epithelium. These are derived from the second and third branchial arches. They are situated generally on the sides of the neck, rarely in front. These cysts may become purulent. There are also rare tumors containing cartilage of the embryonal type. They are common near the ears, and are often bilateral, but are rare in the region of the sternomastoid and very superficial. The author describes three tumors operated on by him. One of these was a carcinoma, one a cyst, and the third contained cartilage.—*Archivio per le Scienze Mediche.*

Book Reviews.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry, Physics, and Toxicology in Cornell University; and TRACY C. BECKER, A.B., LL.B., Counsellor at Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. With the collaboration of AUGUST BECKER, Esq.; CHAS. A. BOSTON, Esq.; Hon. GOODWIN BROWN; W. N. BULLARD, M.D.; G. C. CAMERON, M.D.; J. CLIFTON EDGAR, M.D.; JAS. EWING, M.D.; E. D. FISHER, M.D.; J. C. JOHNSON, M.D.; D. S. LAMB, M.D.; H. P. LOOMIS, M.D.; W. B. OUTTEN, M.D.; ROSWELL PARK, M.D.; J. PARMENTER, M.D.; IRVING C. ROSSE, M.D.; E. V. STODDARD, M.D.; GEORGE WOOLSEY, M.D.; J. H. WOODWARD, M.D. Second edition. Volume One. New York: William Wood and Company, 1906.

OF the importance to the physician of the topics treated in the present work, there can be no doubt; of the general excellence of the handling of these topics there is, also, no room for two opinions. At present we can only give an outline of the contents of the volume under notice, reserving a general review till the completion of the work. The book begins with an historical introduction of twenty-five pages, into which is compressed a large amount of interesting matter, and which represents considerable research on the part of the author. This is followed by a table of the cases cited in the present volume, and this alone is of marked value to the lawyer, and is only one of the many excellent features which differentiate this work from others. The subject of Medical Jurisprudence proper contains chapters on the following subjects: 1. The legal relations of physicians and surgeons, including their duties and obligations; their right to practise medicine and surgery; their legal duties and obligations; their right to compensation; their privileges and duties when summoned as witnesses in courts of justice, and their liability for malpractice. 2. The law of evidence concerning communications between patient and physician. 3. Synopsis of the laws regulating the practice of medicine and surgery in the United States of America, Great Britain, and British North America, with an appendix and a synopsis of the subjects treated in the notes to the laws regulating the practice of medicine. This is by far the longest contribution in the volume, and occupies nearly six hundred pages; unfortunately, it is also the section most liable to get out of date, as the various States are altering these regulations pretty constantly. The section on Forensic Medicine deals with: 1. The legal status of the dead body, the disposal and obligation to dispose of the same; how and by whom it may be exhumed or removed; autopsies, by whom ordered; the rights of relatives and accused persons; including an appendix containing a synopsis of the statutes of the different States and Territories of the United States concerning the same. 2. The powers and duties of coroners and medical examiners; the coroner and his court; the jury and inquest; the effect of the evidence and verdict. 3. Medicolegal autopsies. 4. Personal identity, including the methods used for its determination in the dead and living. 5. Medicolegal determination of the time of death. 6. Death by heat and cold, including insolation, in its medicolegal aspect. 7. Death from starvation in its medicolegal aspect. The volume consists of nearly a thousand pages, and contains information (particularly in the section on Medical Jurisprudence) that every physician should be acquainted with, and with which the law will presume that he is acquainted should he find himself in any situation demanding medicolegal investigation.

SURGICAL SUGGESTIONS. Practical Brevities in Diagnosis and Treatment. By WALTER M. BRICKNER, M.D., Chief of Surgical Department, Mount Sinai Hospital Dispensary; Editor-in-Chief, *American Journal of Surgery*, New York; and ELI MOSCHOWITZ, M.D., Assistant Physician, Mount Sinai Hospital Dispensary; Editorial Assistant, *American Journal of Surgery*, New York. New York: Surgery Publishing Company, 1906.

THESE "Suggestions" are arranged and reprinted from the pages of the *American Journal of Surgery*. They are brief, direct, interesting, and useful.

AIDS TO CHEMISTRY. By T. A. HENRY, D.Sc., Lond., Chief Assistant Chemist, Scientific and Technical Department of the Imperial Institute, South Kensington; Fellow of the Chemical Societies of London and Berlin. New York: William Wood and Company, 1906.

THIS little volume contains a carefully-prepared outline of both inorganic and organic chemistry. It differs from most books of its class, in that it really contains a large amount of chemistry. As an aid to following lectures in college it will be of considerable service, though it is not written from the standpoint of the medical student. To those preparing for the various State board examinations this book will be of little or no use; for, in the first place, it contains much more chemistry than any State board requires; and, further, it omits not only the chemistry of urine, gastric juice, etc., but also a large amount of elementary matter, definitions, general principles and laws, nomenclature, etc. Though small, this work is by no means elementary, and it can be recommended to all who desire a compend that is first class and up to date.

A NON-SURGICAL TREATISE ON DISEASES OF THE PROSTATE GLAND AND ADNEXA. By GEORGE WHITFIELD OVERALL, A.B., M.D., Chicago. Rowe Publishing Co., 1906.

THIS volume contains an account of the author's conservative treatment of the diseases of the prostate gland and its adnexa. As the book is in its third edition, it is safe to infer that it has been found useful. In a future edition the occasional Latin expressions should be either corrected or omitted; such phrases as *ad nauseum*, *bacho et venere*, and *impotentis caeundi* do not appeal favorably to the educated reader.

TECHNIQUE DU TRAITEMENT DE LA LUXATION CONGÉNITALE DE LA HANCHE. Par le Dr. F. CALOT, Chirugien en chef de l'Hôpital Rothschild, de l'Hôpital Cazin-Perrochano, d l'Hôpital de l'Oise et des departements, du Dispensaire, de l'Institut orthopédique de Berck, etc. Avec 206 figures dans le texte et 5 planches (en photocollographie). Paris: Masson et Cie., 1905.

THIS manual on the treatment of congenital dislocations of the hip is the second volume of the author's work on orthopedics. The first volume dealt with hip joint disease; the third will deal with white swelling, and the fourth will cover the subjects of Pott's disease, scoliosis, infantile paralysis, club-foot, torticollis, tarsalgia, spastic paraplegia, rachitic deformities, etc. The author is of opinion that congenital dislocations of the hip can, and should, be cured up to the twelfth or fifteenth year by the bloodless method. The present volume thoroughly discusses the malady in question, and pays particular attention to the diagnosis of the trouble and its prognosis; the various methods of treatment are also given in considerable detail.

PHYSIOLOGY OF THE NERVOUS SYSTEM. By J. P. MORAT, of the University of Lyons. Authorized English Edition, translated and edited by H. W. SYERS, M.A., M.D. (Cantab.), Physician to the Great Northern Central Hospital. With 263 illustrations, 66 in colors. Chicago: W. T. Keener & Co., 1906.

THE present volume is a translation of that portion of the Treatise on Physiology, by Professors Morat and Doyon, which is devoted to the functions of innervation. The subject is a complicated one, at the same time it is one often neglected by the practitioner and inadequately handled in the text-books on general physiology; hence we can welcome the present work, which embodies the latest advances in the knowledge of the nervous system, and contains the most recent views and ideas on this intricate branch of physiology. The first part of the volume deals with elementary nervous functions, and consists of two chapters. The first chapter treats of the nervous element, and handles in turn the static conditions of the neuron; anatomical and physiological data; dynamic conditions; functions of the neuron; stimulation of the nerves; and the laws of electrical stimulation. The second chapter is on energies of the nerve, and discusses energies recognizable in the nerve; electrical energy; consecutive effects of stimulation; fatigue; electrotonus; different employment and effects of electricity; and nerve poisons. The second part of the book is on systemic functions, with chapters on sensibility and motion, with their relations; primary systematizations; consciousness and unconsciousness; and superior systematizations. The last section in the volume is on specific innervations, and contains chapters on tactile, visual, auditory, olfactory, and gustatory innervation. There is a concluding chapter on language and ideation.

ECZEMA. A Consideration of Its Course, Diagnosis, and Treatment, Embracing Many Points of Practical Importance, and Containing 146 Prescriptions, Illustrating Dosage in Local Applications. By SAMUEL HORTON BROWN, M.D., Assistant Dermatologist, Philadelphia Hospital; Dermatologist, Southern Dispensary; Assistant Dermatologist, University Hospital Dispensary, etc. Philadelphia: P. Blakiston's Son & Co., 1906.

ESPECIAL attention is paid by the author of this book to the treatment of the disease. The writer refers in his preface to the dogmatic manner in which some of the facts have been presented, and he explains his method of presenting the subject by the fact that any statement, no matter how true, loses weight when qualified. Thus, instead of the vague directions so common in books of this nature, the reader finds explicit directions for the care of different types of eczema. The treatment of the disease in various regions comprises a very helpful section. A good index completes this convenient little volume.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 4, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Orthopedic Surgery.

Presentation of Instruments Illustrating the Historical Development of Laryngological Technique.—Dr. D. BRYSON DELAVAN made this presentation. (See page 612.)

Presentation of Portraits of Sir Thomas Watson and Sir Andrew Clark.—Dr. CHARLES L. DANA presented these portraits to the Academy.

Nontuberculous Joint Diseases, with Especial Reference to the So-Called Rheumatic Affections.—Dr. ROBERT W. LOVETT of Boston read this paper. He said that the last twenty years had seen a very decided change in our views as to the pathology and classification of joint disease, and the salient features of the change in view occurring in these twenty years were three in number. First, tuberculous joint disease had resumed a more rational position and no longer overshadowed the field, because it was not a newly-recognized, but a well-established and studied affection, and because many cases formerly classed as tuberculous disease had been recognized and placed in their proper categories. Second, the term rheumatism had been subjected to scrutiny and analysis. The adjective rheumatic had done more and was doing more to retard the rational study of joint disease than any term in use; in the past it had been a name to cover all sorts of conditions, and even to-day was to a certain extent accepted as sufficient explanation of almost all obscure cases of joint inflammation. Third, infection played a very important and prominent part not suspected years ago. It had been recognized that acute serous synovitis might be caused by infection. and it had been suspected that infection had much to do with chronic nontuberculous joint disease in general. The study and investigation of acute articular rheumatism had led to the conclusion that many, if not all, cases of so-called acute articular rheumatism were of infectious origin, and that the source of infection might be found (*a*) in some general infectious disease, such as scarlatina; (*b*) in some local infection, as the nasopharynx, mastoid, or appendix; (*c*) in the free entrance of bacteria through the tonsils, especially if they were inflamed. A serous joint inflammation of undoubtedly infectious origin was frequently identical clinically with one arising without obvious source of infection. Osler said: "In the character of the fever, the mode of involvement of the joints, the tendency to relapse, the sweats, the anemia, the leucocytosis, and above all the great liability to endocarditis and involvement of the serous membranes, acute rheumatic fever resembles very closely pyemia, and might, indeed, be taken as the very type of an acute infection." In examining the fluid of diseased joints of any kind for bacteria, it must not be assumed that the absence of organisms established the existence of non-infectious source of the joint effusion. It was assumed in these cases of undoubtedly infectious origin that toxins rather than the bacteria themselves were the direct cause of the joint inflammation. The importance of negative bacterial results should not be overestimated. Organisms of various types had been found in the joint fluid in the endocardium and in other structures in cases of so-called acute articular rheumatism, but the constant association of any type of microorganism with the disease had not been established. Staphylococci, streptococci, and organisms resembling streptococci had been found and given various names, as diplococcus rheumaticus, micrococcus rheumaticus, etc. Accepting these findings as undisputed, one of the three following assumptions must be true: First, so-called articular rheumatism was a specific infectious disease of unknown origin, the cocci being secondary; second, there was no such specific disease, and it must be regarded as a general streptococcus infection; third, it was due to a specific form of streptococcus, which from its clinical behavior must possess special characteristics. We could not at present judge whether the disease was caused by a specific microorganism, and this question was secondary to the question of the infectious origin of so-called acute articular rheumatism. The cocci found in acute articular rheumatism, when inoculated intravenously into susceptible animals, had caused myocarditis, pleuritis, pericarditis, endocarditis, iritis, chorea, and joint effusions, lesions identical with those found in so-called acute articular rheumatism. These results had not as yet been constant. At times inoculation experiments of this kind were negative, and at other times the result was suppuration. Such was the evidence preponderatingly in favor of the infectious character of so-called acute articular rheumatism. It would be better if we spoke of the articular manifestations called acute articular rheumatism as "acute synovitis, probably infectious."

The subject of chronic nontuberculous joint disease was one which was singularly obscure and confused. From the general discussion he omitted syphilitic joint disease, gonorrheal arthritis, the joint affections of organic nervous disease, gouty joints, the joint disease of hemophilia, and the joint disease resulting from malignant disease and actinomycosis. After eliminating these, there remained a group which were in general subacute or chronic, characterized by joint pain and swelling; they were nonsuppurative, generally progressive, and characterized by exacerbations and remissions, and were liable to result in disability or deformity if untreated. These cases might be polyarticular or monarticular, and they might occur at any age after infancy. In a most casual glance over current literature he had found forty-eight names for this class of cases or for parts of it, including foreign synonyms or obsolete names. We were familiar with the group or its members under the names of rheumatoid arthritis, rheumatic gout, chronic rheumatism, osteoarthritis, etc., etc. There was no agreement as to a name for the group or as to existing classification. He recalled the fact that but a few years ago there were many names describing tuberculous joint disease, while to-day one heard but the one name. On the subject of nontuberculous joint disease the medical community seemed to have gone classification-mad, and he pleaded for greater simplicity. Provisionally he would call the whole group arthritis deformans. The gross pathological changes found in these cases consisted of one or more of the following types: (1) Chronic serous synovitis, with thickening of the synovial membrane. (2) The development of synovial villi. (3) Ulcerative arthritis, with destruction of areas of the joint cartilage. (4) The formation of ankylosis. (5) The proliferation of bone around the joint margins. The fibrillation of cartilage was frequently associated with all of these conditions, and the types might be associated clinically in any combination. Certain cases of chronic arthritis deformans had their onset during the occurrence of a general infectious disease. The onset in many cases was indistinguishable from what was called acute articular rheumatism. Schüller had described a dumb-bell bacillus which he associated wholly with the form characterized by villi. They could be cultivated, and when isolated would cause similar joint affection in animals. He cited a number of investigators who had found bacilli in the synovial fluid in cases of this class. Trauma was recognized as a localizing cause of certain cases of arthritis deformans. He reviewed the nervous theory, which assumed that the pathological changes were due to reflex nervous disturbances in the spinal cord. He also spoke of the metabolic theory, which assumed a dyscrasia, or disturbance of metabolism, as the cause of changes, the symmetry of the lesions and the general

symptom complex being the basis of the theory. Examination of excreta had failed to give support to this theory. Two or more etiological causes under certain conditions were capable of producing one or more of five pathological results. The etiological sources bore no constant relation to the pathological results. The pathological results were grouped in no constant relation, either to the etiological causes or to each other. Such being our limited knowledge, it would be an advantage to have a classification which did not overrun the boundaries of our knowledge. It was well known that there were distinct clinical types frequently seen, and it was safer to assume that these were types rather than separate diseases, until the entity of each separate disease was proved. In short, he advocated the view that until proven by sufficient evidence to be separate diseases, the conditions which he had spoken of as types of arthritis deformans should be spoken of as arthritis deformans with proliferation of bone, arthritis deformans of the ankylosing type, etc., and that separate diseases should be recognized only when their entity had been established by the same class of evidence that we would accept as valid in other departments of medicine and surgery, namely, by discovery of their etiology.

Fortunately our treatment of this class of diseases was far in advance of our theoretical knowledge of their causes and relation to each other. We had ceased to impoverish the patient by irrational diet, and we realized that salicylate of sodium and iodide of potassium did not cure arthritis deformans. The cardinal points of modern treatment were now recognized as (*a*) nourishing diet of the kind best assimilated by the patient, supplemented by tonics, if necessary. (*b*) Regularity of the daily routine in the avoidance of overwork and exposure, and the establishment of proper hygienic surroundings. (*c*) Stimulation of the elimination of waste products by the skin, kidneys, and bowels. The local measures aimed at checking the process in the joint by the avoidance of undue traumatism, the restoration of the local circulation, and the stimulation of the muscle controlling the joint. (*d*) The great importance of rest as a curative factor during periods of irritation had been brought to notice by Gibney and Sayre. (*e*) The local circulation was to be stimulated and the muscular condition improved by massage, baking, douches, and electricity. (*f*) The treatment by congestion of these parts, as described by Bier, deserved especial mention. (*g*) If obstruction existed in the way of tumors or bony outgrowths to the extent of causing disability, they should be removed by surgical measures. (*h*) If any ankylosis occurred at a vicious angle, the limb might be straightened. The relation of arthritis deformans to so-called acute articular rheumatism was a question which we could not settle as yet. This was a problem to be settled in the near future. He advocated restricting our classification to our facts, subdividing only so far as data justified us in so doing, and in the meanwhile to use a fairly unobjectionable term.

Bone Syphilis, Hereditary and Acquired.—Dr. Robert W. Taylor read this paper. In speaking of early and late hereditary syphilis he said that heretofore these lesions had been summed up in two words, osteochondritis and periostitis, but that now we had to include many and varied conditions. Acquired syphilis induced in the offspring two conditions: First, a syphilitic heredity, in which the morbid processes were not specifically luetic, but were the result of a general dyscrasia which lowered the vitality and more or less impaired, retarded, or vitiated the nutritive processes, and to which the term dystrophic lesions was given; and, secondly, true virulent hereditary syphilis, in which the virus penetrated the whole body and produced its protean lesion. As instances of hereditary syphilis affecting the bones, one found affections due to backwardness of development, arrest of development, and imperfect development. In the category of hereditary syphilitic lesions one found osteochondritis, osteitis, osteoperiostitis, gummatous osteoperiostitis, and gummatous osteomyelitis. As correlated to bone lesions, one found arthropathies in the form of mild and chronic synovitis and deforming synovitis, with more or less destruction of joints and involvement of the juxtaarticular osseous tissues. Dr. Taylor confined his remarks to the study of the specific lesions of hereditary syphilis, and the earliest, most extensive, constant and notable lesions were those due to osteochondritis. The changes here seemed to be proliferative, and had not the character of gummatous infiltration. The swelling might develop slowly or rapidly; after reaching their full size, they usually remained in an indolent condition, causing little pain and interfering but slightly with the motion of the joint. Under appropriate treatment they subsided. Degenerative changes sometimes took place in these osseous lesions. The bones most commonly affected were those of the forearm, the leg, the arm, and the thigh. It was exceptional for the victims of multiple bone lesions to survive. Dactylitis syphilitica was then considered, these lesions having the same character as those of acquired syphilis, namely, an osteitis and osteomyelitis. Swellings of the metacarpal and metatarsal bones usually occurred quite early in hereditary syphilis, and might or might not exist with dactylitic enlargements. They might appear as late as the twentieth year. Dr. Taylor reported in detail a case in which the lesions were osteitis, periosteitis, gummatous periostitis, and osteomyelitis, and the sequelæ were atrophy and loss of bone, elongation of a long bone, and ankylosis of joints and eburnation. Fournier had pointed out an important diagnostic feature, that in the late forms of inherited bone disease there was a decided tendency to the involvement of the terminal extremities of the diaphyses. In most cases of hereditary syphilitic bone lesions, particularly when the shafts were attacked, there was more or less pain, some parents looking upon them as growing pains. It was a good rule to suspect hereditary syphilis in any bone lesion accompanied by pain, mild or severe, continuous or paroxysmal. Several cases of late hereditary syphilis with elongation of long bones have been described under the title of partial or local gigantism. Few cases of general gigantism were on record. Hereditary syphilis of the joints was seemingly little understood, and yet it was not of infrequent occurrence. The larger ones were usually involved. The lesion in older children seemed to be an irritative inflammation with more or less effusion, usually without bony involvement, and which subsided coincidentaly with the involution of the exciting cause in the bone structures. In later life, from the sixth to the eighth year onward, synovitis which might be called primary was observed. The affection developed in a slow and insidious manner, ran a chronic course, with little, if any, pain or redness in most cases, allowing some freedom of motion, and showing great tendency to relapse. He stated that syphilis and tuberculosis seemed to go hand in hand together in their lethal course, and many observations had been made of tissues in which this symbiosis existed. It seemed that syphilitic tissues formed a prolific culture field for the bacillus of tuberculosis. So in all cases one should be on the lookout for this second invasion. Dr. Taylor closed his paper with a consideration of the diagnosis of bone and joint hereditary syphilis.

Dr. Henry Ling Taylor said that an extremely common form of joint affection was the gonorrheal, and this might be mono- or polyarticular, and it might appear at any period, even months or years after. Many of the joint affections occurring in the young adult would be found to be due to a gonorrheal infection if the etiology was closely analyzed. He referred to one form, the painful flat-foot, or tarsalgia. This might be associated with osteophytes. Syphilitic bone lesions were not so often found when one considered the prevalence of syphilis. The antirheumatic treatment was usually harmful, and, in the care of these cases, the main indication was to improve the nutrition.

Nontuberculous joint lesions were masquerading under various designations.

Dr. Eugene Fuller said that, in gonorrheal rheumatism, for a number of years he had been draining the seminal vesicles; this seemed to be especially efficacious in those chronic cases in which there was pain and distress, and which would not yield to the ordinary forms of treatment. He looked upon the seminal vesicles as he did upon other cavities in the body. After doing this operation upon many cases and getting good results, he came across a man in the City Hospital who had had, for four months, gonorrheal rheumatism; the seminal vesicles were tumefied and the patient was in a bad condition, perfectly helpless. He drained the seminal vesicles, which resulted in the pain and distress disappearing and the toes could be moved with freedom, a thing he could not do prior to operation. In two and a half weeks the patient was up and around the ward. This case made Dr. Fuller so enthusiastic that he since had operated upon thirteen others for gonorrheal rheumatism. In these fourteen cases he got immediate relief from the rheumatic symptoms. Out of the fourteen cases there were nine cures. Of the five not cured, two left the hospital free from pain and perfectly comfortable; they sprang into alcoholic and sexual excesses, causing a recrudescence. These two cases should be placed among the cures. In the other cases drainage was not kept up long enough, although the results were encouraging.

Dr. John Rogers, Jr., said that few cases of gonorrhea ever got up any systemic infection; but when they did, the joints usually became involved. In a certain class of cases the patients appeared to be cured by some special protection given the organism, and the inference was that this protection was given by some antibody or serum. There appeared to be three classes or groups, viz., (1) those which quickly subsided; (2) those which lasted from six weeks to four months; and (3) those which continued indefinitely for years. In the first and second groups the patients recovered because of some protection given by the organism; if they recovered, it must be because of their own protection. The use of serum in these cases seemed to give encouraging results. The serum he had used was obtained from rabbits, and in this connection it should be borne in mind that rabbit's serum was poisonous to certain people. Injections were given in the back of the arm.

Mr. Torrey reported a series of cases of gonorrheal rheumatism treated with the serum during the past year, 55 in all. There were 39 acute and subacute, and 16 chronic cases. Of this number, 34 (61 per cent.) were cured by the serum. Of the remaining 21 cases, 12 were improved, and in nine there was no change. Of the acute and subacute cases, 39 in all, 31 were cured (79 per cent.); of the remaining 8, 3 were improved and there was no change in 5. The serum was of marked benefit in only a small percentage of the chronic cases, but of great benefit in the acute and subacute cases. In 28 the condition was monoarticular; in 27 polyarticular. They were of all degrees of severity and 18 had been treated before without any improvement. When the injections were given there was a rise in temperature of from one to two degrees, with slight pain in the head and back, especially in the chronic cases.

Dr. Joseph Collins said that arthropathies accompanied chronic or organic nervous diseases, and that Dr. Mitchell, Sr., had described the joint changes of tabes seventy-five years ago. All recognized in tabes and syringomyelia that from 8 to 12 per cent. of all cases developed painless enlargements of joints. Oftentimes in organic nervous disease, as of the peripheral nerves, such as a neuritis, there were changes in the joints, especially of the wrist and ankles, giving certain alterations named arthritis deformans, and such arthropathies were worthy of an adequate description in the literature. These arthropathies were not well marked in cerebral diseases. Dr. Collins also discussed arthropathies and hysteria. Of 10,000 cases on record, only two of hydrops intermittens were recorded which might be classified as chronic enlargement of the joints. Dr. Collins was loath to accept the classification as given by the reader of the paper.

Dr. Royal Whitman spoke of one minor form of joint affection, the overweighted joints. A patient weighing 200 pounds who should weigh 135 might have a so-called rheumatoid arthritis of the knees, no other joints being involved. Here the remedy was to reduce the weight.

Dr. Lovett, closing the discussion, said that the word rheumatism, as used by the general practitioner, should be avoided. All he asked for in the matter of classification was that they should have a provisional class for the unidentified cases until they were identified. The classification he presented was merely a provisional one.

SECTION ON SURGERY.

Stated Meeting, Held May 4, 1906.

Dr. John F. Erdmann, Chairman pro tem.

Bronchoscopy and Removal of a Foreign Body from the Right Bronchus.—Dr. Charles A. Elsberg presented a child who, thirty hours before admission to Mount Sinai Hospital, had swallowed a pin about one and a half inches long, its head going first. She immediately after began to retch, vomited bloody mucus, and complained of pain and discomfort in the chest. These symptoms disappeared after a few hours. She was kept on a fluid diet and the stools were carefully watched for the pin. There was no pain on swallowing, nor other symptoms. When admitted to the hospital there were some peculiar bleating sounds over the lower part of the right chest behind. The *x*-ray revealed the pin with its head downward in the fifth intercostal space, a little to the right of the middle line. Three days after admission Dr. Emil Mayer passed the bronchoscope, but could not find the foreign body. Dr. Elsberg then did a low tracheotomy, passing a moderately sized endoscopic tube through the tracheal opening and into the right bronchus. The pin was at once seen lying in the right bronchus. Its shaft could be followed upward for about one-half an inch until it became buried in the wall of the bronchus. All efforts to free the point of the pin were unsuccessful until he did as follows: The shaft of the pin was grasped with slender forceps as far away from the head as possible and the endoscopic tube then pushed down, the pin being firmly held by the forceps. Thus the head of the pin was freed from the wall and the shaft of the pin gradually bent into view, until the point was swept into the left bronchus. By repeating this procedure the pin was bent upon itself and, with the head and the point both pointing downward, could be grasped at the angle and easily extracted. A tracheotomy tube was then inserted; this was removed at the end of a week and the wound healed rapidly. Convalescence was interrupted by an attack of measles.

Dr. Elsberg presented another patient who had had a turkey bone in the right bronchus. Coughing persisted for weeks and with a mucopurulent expectoration. Very interesting signs were noted in the chest. Dr. Janeway made a positive diagnosis of foreign body. The *x*-ray examination was negative. There was a large amount of peribronchial exudation. Expiration began with an amphoric sound and ended by a hissing one. The temperature was irregular. Much flesh and strength was lost. Under chloroform anesthesia a low tracheotomy was done and the foreign body, a piece of turkey bone, was found in the middle one of the three branches of the right bronchus. There was no trouble experienced in grasping it with the forceps and removing it. Pictures were presented showing the position of the bone in the bronchus.

Laparotomy and Suture of Bleeding Duodenal Ulcer.—Dr. Elsberg presented this patient, a man, 31 years old,

who had had an operation performed for some gallbladder trouble. He came into the hospital with a long history of intestinal symptoms, tarry stools, etc. The physical examination revealed nothing. He complained of pain in the gastric region and tarry stools. Hemoglobin was 94 per cent. and dropped in four hours to 60 per cent., and by the evening of the same day it was 50 per cent. An operation was done at once for supposed duodenal ulcer. The gall-bladder and mass of intestines were bound together by adhesions and the duodenum was much infiltrated and opened into an ulcer. He attempted to bring the parts of the ulcer together, but the parts were too fragile. After operation the patient improved rapidly, but later there occurred a leakage of fecal contents. Two hours later he was again operated upon, but no ulcer was found, only a hole in the duodenum. The duodenum was immobilized according to Kocher's method and the transverse colon was then implanted upon the duodenum. The wound was closed with drainage. The wound healed well and there was no further leakage. The hemoglobin now was 85 per cent. The great fall of the hemoglobin made the operation justifiable.

Dr. JOHN A. HARTWELL reported a case of gastric ulcer occurring in a man 35 years old who was admitted to hospital the second time. He gave a history of bleeding for three or four months before coming to the hospital the first time. He remained three weeks and went out again much improved under medical treatment. After several severe hemorrhages he again entered and the hemoglobin was then 40 per cent. He was kept under observation for four or five days and was improving. After the sixth or seventh day the hemoglobin was 50 per cent. and no hemorrhages. There was no pain or other gastric symptom. That night he died, apparently from acute hemorrhage. At autopsy no ulceration or even suggestion of ulceration was found anywhere in the alimentary tract. Nothing was discovered to cause either the original bleeding or death.

Dr. JOHN F. ERDMANN said that he had had twelve or thirteen cases of perforating ulcer of the pyloric end of the stomach and in none was there any preliminary hemorrhage at all, no hemorrhagic evidences whatever.

Recurrent Sarcoma of the Outer Table of the Skull; Disappearance under X-Ray Treatment.—Dr. ASPINWALL JUDD presented this patient, a woman, with a recurrent sarcoma of the outer and beginning involvement of the inner table as well. Forty-two exposures (three a week) were made, using a high tube at a distance of nine inches. There were no burns and there followed a complete disappearance of the tumor. He did not claim a cure, only a disappearance of the sarcoma.

Dr. LEWIS GREGORY COLE discussed this case.

Tendon Implantation with Restoration of Function in the Hand.—Dr. JUDD presented a little girl who had had a suppurating wound involving the tendon of the communis. He cut down upon this tendon and found it retracted so that he could not bring the ends together. He then made an incision in the tendon of the indicis and stitched it to the communis tendon with silk, surrounding the parts with Cargyle membrane. There was complete immobility of the middle fingers of the hand; at present the movements were perfect. Passive motion was resorted to early.

Dr. REGINALD R. SAYRE congratulated the doctor upon the good results obtained.

Local Anesthesia in the Operative Treatment of Anorectal Diseases.—Dr. S. G. GANT read this paper. He said that since he had advocated local anesthesia in the operative treatment of minor affections of the lower bowel, 1,200 cases had been operated upon at the clinic, office, or home of the patient. Some of the operations were of minor importance, while others were of considerable magnitude. The conditions for which operations were performed embraced nearly all the diseases encountered about the rectum and anus. While local anesthesia could undoubtedly be successfully employed in a great many radical operations, he was convinced that it was not for the best interest of the patient to employ it to the exclusion of general anesthesia. The administration of a general anesthetic was imperative for all operative procedures in the upper rectum, and all extensive operations such as were required to remove large tumors or to relieve complete extensive prolapsus recti, complex, horseshoe, rectovesical, rectourethral, and rectovaginal fistulæ, very extensive abscesses, necrosis of the coccyx and sacrum, and strictures and congenital malformations above the internal sphincter muscle. General anesthesia was also necessary in operations for fistulæ, hemorrhoids, fissure, abscess, etc., complicated by other more serious rectal disease, when the local anesthesia did not permit the diseased tissues to be sufficiently exposed for thorough operation, when the areolar tissue was loose and allowed the solution to disseminate rapidly, and when a sufficient amount of the fluid could not be retained to cause pressure and blanching of the tissues. The above-named affections constituted but a small proportion of the total number of cases coming under the proctologist's care. The local anesthetics employed by the writer were, in the vast majority of cases, sterile water, eucaine, and cocaine. In the cases operated upon by the aid of water anesthesia, the anesthetization of the parts was produced by the injection of either a physiological saline or a plain sterile water. They were equally effective in producing anesthesia, and the pain caused by the distention was not noticeably more from one than from the other. The temperature of the water played no part so far as the anesthesia was concerned, but there was less discomfort when it was at the temperature of the body. The distention of the tissues with water had never caused sloughing in his experience. Postoperative pain was more severe and lasted longer with eucaine and cocaine than when sterile water was used. At present he employed eucaine and cocaine in strengths ranging from one-eighth to one-twentieth of 1 per cent. The technique was the same whatever the agent employed. The anesthetic should not be injected too suddenly or in a larger amount than was required, nor should the needle be made to enter one place and then another. When a linear incision was to be made the anesthetic should be slowly injected between the layers of the skin along the line to be incised, after which the needle should be pushed further in and the deeper tissues anesthetized. In divulsion of the sphincter muscle a one-tenth of one per cent. eucaine or cocaine solution was preferable to sterile water. In order to ascertain to what extent sterile water was being employed in operations about the rectum and anus, a letter was sent to members of the American Proctologic Society and a few other specialists, asking for the number and variety of cases operated upon, the results obtained, and their opinion of sterile water as a local anesthetic. A study of the letters received and a study of the statistics obtained, together with a large experience of his own, proved that plain or saline sterile water was a safe and reliable anesthetic, and that it had a wide range of usefulness.

Dr. JAMES P. TUTTLE said that his experience with this method had not been at all satisfactory and possibly he might have injected the water too fast. The pain in operating upon external hemorrhoids was very great, but not so excessive in operating upon internal ones. The injection of water or saline solution so distorted the parts that one could tell with difficulty what one was doing; the injection alone produced a tumor like a hemorrhoid. In dealing with moderate degrees of hemorrhoids, prolapsus, or fissures, he believed that local anesthesia was a very useful addition to surgical practices. But he could not indorse this method in operating upon fistulæ; all fistulæ, even of the simplest type, he believed, should be operated upon only under general anesthesia. It was safer to operate upon a patient at his home or in the hospital than to attempt to do so in the office.

Dr. Hill said that two years ago he started this method of local anesthesia at the Boston dispensary. There was no great choice between eucaine or cocaine solutions.

Dr. A. Ernest Gallant said that the differences of opinion regarding the effects produced by these various solutions might be attributed to the manner of introducing these drugs. If one got the solution under the skin, so raising the epidermis, anesthesia would result.

Excision of the Rectum for Cancer with Preservation of Normal Anus.—Dr. William C. Lusk showed twenty-five charts illustrating the anatomy of the pelvis relating to excision of the rectum, uterus, and part of the vagina. The studies were made with a view of determining the possibilities of a wider removal of the pelvic tissues in cancer of the rectum. The writer stated that though uncertain about the practical applicability of the proposed operation, anyway he felt he was making no mistake in furnishing this contribution to the anatomy of the pelvis, and the work might stimulate a train of thought for an improved operative technique in the removal of the rectum. The case reported had an anteriorly situated colloid carcinoma, its lowest palpable limit being one and one-half inches above the internal sphincter. The approach for the removal of the disease was both through the coccygeoperineal region and by a median celiotomy wound. The coccyx was removed, but the sacrum was not resected. The muscular coats of the bowel were sectioned below, just above the internal sphincter, and the inner coat, after having been shelled out of the anal canal, was cut off at about the pecten. The proximal end of the sigmoid was brought through the sphincters and sewed to the divided anal margin, a clamp being left on the bowel and retained there for thirty hours. The peritoneal reflection onto the uterus and the tissues attached laterally to the rectum were invaded, but below, the bowel was severed in healthy tissue above the internal sphincter. The bowel end sloughed, a vaginal fistula resulted, and the patient recovered with a stricture of the anal canal. The contractility of the external sphincter was not impaired, and the patient was comfortable up to the end of April, when, through neglect on her part, the stricture contracted. Dilatation relieved the immediate symptoms. All of the cancerous tissue was not removed. Statistics would seem to show that in about one-half the cases of rectal cancer the sphincter was not invaded. The contention for saving it where possible was mainly for the preservation of the pelvic floor. The importance of using clamps and cautery for the avoidance of infection in resecting the bowel was emphasized. An absolute necessity in operating in the pelvis through the abdominal incision was the Trendelenburg position. As a matter of operative technique, so far as a single trial on the cadaver had shown, it would seem quite feasible to commence the operation from above through a median abdominal operation, and complete the operation through the lower wound, either primarily or at a subsequent séance. In connection with the abdominal incision there arose the question of preliminary colostomy. If this was practised a subsequent abdominal incision would of course be interdicted. Illustrations were shown demonstrating how the middle hemorrhoidal (when present) and vaginal arteries, together with the branches from the third and fourth sacral nerves which joined the inferior hypogastric plexus of the sympathetic, could be tied close to the pelvic wall through the coccygeoperineal wound. The latter approach was laid open by a horseshoe-shaped flap over this region, followed by the removal of the coccyx and splitting of the levator ani in the median line. Illustrations also showed a method of separating the ureters from the sides of the vagina, which was done through the abdominal incision. It seemed that a systematic plan of tying the vessels of the mesosigmoid, when it was to be divided and mobilized, would improve the technique of the treatment of this portion of the bowel. There were two structures of the mesosigmoid which limited the distance to which the proximal end of the severed sigmoid could be carried. One of these was the entering vessels, and the other was the peritoneum. The chart showed how the intact sigmoid artery could prevent carrying the end of the divided sigmoid to a distance greater than the length of the vessel. Therefore to mobilize the end of the sigmoid this vessel must be divided. The restraining peritoneum should be cut on either side near the root of the mesosigmoid independently of the vessels, and should not be included within the grasp of any of the ligatures. In order to preserve the nutrition of the portion of the sigmoid to be mobilized it seemed that the principle could be laid down both that the entering trunks of the vessels should be tied, and that the peritoneum should be severed at the root of the mesosigmoid, so as to leave the vascular arches which should receive collateral circulation from above, attached to the freed portion of the bowel.

Wyeth's Amputation for Sarcoma of the Femur.—Dr. A. Ernest Gallant showed a specimen which was removed from a woman 23 years old. She fell and bruised her knee and later a diagnosis was made of either sarcoma or gumma. The radiograph indicated a fracture of the femur, and the limb was splinted. At the end of one month an incision was made and examination proved the tumor to be a mixed celled variety of sarcoma. Amputation was then performed by Wyeth's method. The case was of particular interest because the *x*-ray failed to show anything.

Dr. Lewis Gregory Cole showed an *x*-ray plate of the limb after removal which showed very distinctly where the normal tissue ended and the diseased tissue began. Dr. Cole also showed an *x*-ray picture of a benign sarcoma which was very clear and distinct, the lesion being readily detected.

Mastitis in the Aged.—Dr. A. Ernest Gallant showed two specimens, one removed from a patient 59 years old, the other from one 71 years old. Inflammation in both cases started in the region of the nipple. One consisted of an intracanalicular fibroma; the other was reported to be an intracanalicular fibroma with a general mastitis. Dr. Gallant said that cases of intracanalicular fibroma were rare.

AMERICAN ASSOCIATION OF GENITOURINARY SURGEONS.

Twentieth Annual Meeting, Held in New York City, June 1 and 2, 1906.

The President, Dr. F. Tilden Brown of New York, in the Chair.

(Special Report to the Medical Record.)

First Day—Friday, June 1.

An Apparently Healthy Child Born to Parents, Both of Whom Were in the Active Stage of Syphilis.—Dr. Alfred C. Wood of Philadelphia reported this case. Mrs. X., aged 28, housemaid, married three weeks, had a syphilitic lesion on the right half of the upper lip. There was general glandular enlargement and roseola. She left the hospital on June 24, after having been there for nearly two months, and at that time was taking pills of protiodide of mercury. The following May the patient was delivered of a perfectly healthy male child, weighing about eight pounds. The child had never shown the slightest evidence of anything but the most perfect health. He had been fed from the mother's breast, slept well, and had thrived as well as any child could. As this child had completed his thirteenth month without mishap, the likelihood of specific manifestations might be considered very remote. The husband suffered from syphilitic dactylitis. The only history that could be elicited from him was that about two years before he had had a sore on the left side of his lower lip, "inside and out." The sore was cauterized, after which it healed.

No history of secondary manifestations could be obtained.

Dr. L. Bolton Bangs of New York said that Dr. Wood had taken it for granted that the sore in the mouth of the man was the initial lesion. If that was the case, was the bone lesion not a rather early one, following the initial lesion in the mouth? He raised the question whether it was not possible that the woman acquired the syphilis from some other source.

Dr. George K. Swinburne of New York knew of no preparation of mercury which gave such a large proportion of bad results in the long run as protiodide of mercury. He thought mercury should not be given by way of the stomach. He cited an instance in which a mother was infected with syphilis at the seventh month of pregnancy and showed all the manifestations of the disease before the birth of the child, and yet that child never showed any syphilitic lesions at any time.

Dr. John Van der Poel of New York said that his experience with the protiodide corresponded with that of Dr. Swinburne. He had seen instances in which, after the administration of large doses of protiodide, secondary, and even tertiary lesions, had appeared. He advised injections of mercury, or else its use by way of the skin. For injection he preferred the biniodide to the cyanide of mercury.

Dr. E. C. Burnett of St. Louis said that, in regard to the case cited, he thought the father gave a clear history of syphilis. So far as the child was concerned, he thought it difficult to make a prognosis. Syphilitic lesions in the tertiary form were often developed during adolescence in which there was no history of infection.

Dr. Wood said that one point in regard to the husband's having infected the wife was that his lesion was on the left side of the mouth, while that of the wife was on the right side. He expressed surprise at the general condemnation of the protiodide of mercury. He stated that one of the most prominent syphilographers in this country claimed that he cured 95 per cent. of these cases with this salt of mercury.

The Antigonococcus Serum of Rogers and Terry in Epididymitis.—Dr. George K. Swinburne of New York read this paper, in which he said he had been led to experiment with this serum in the case of a man, 34 years of age, whom he had been treating for a primary acute attack of gonorrhea. The right knee became affected, and the patient, being unable to remain at home, was sent to Gouverneur Hospital. A week later he was completely cured so far as the knee was concerned. A little later the author saw this case reported in a current periodical, and learned that the rapid recovery was due to the use of antigonococcus serum. He had heard several who had used the serum in gonorrheal rheumatism express themselves as not being favorably impressed, and he had also heard that it was a failure in epididymitis. These failures were to be expected until further experiments had been made. Thirteen cases were reported in detail. To be effective the serum ought to be administered early in the course of the disease. Seven of his cases were treated within twenty-four hours of the beginning of the epididymitis. The trouble had lasted for from three to four days in four of the cases. Three of the patients received two injections, 24 and 48 hours apart. These made an apparently complete recovery within a few days, but, suffering a slight relapse, another injection was made. Two received two injections, four received three injections, three received four, and two received five. He had tried the injections in the abdomen, as was done at first, but preferred the back of the arm, which was previously scrubbed with bichloride and alcohol. Of course, the needles and syringe were carefully sterilized. In no case was the local reaction attended with any disagreeable sequelæ. There was no trace of the disease in three cases. In two there was a rather long, soft mass left about the epididymis. He concluded that the serum had exerted a distinct effect in all the cases, and that the disease was distinctly modified and the duration shortened. In several instances the recovery was remarkable.

Dr. L. Bolton Bangs of New York said he was somewhat skeptical in regard to the use of the serum. Even without the serum one could assure a patient that he would probably have but four days of pain, but one could not promise that the swelling would subside in that time.

Dr. Edward Martin of Philadelphia said that he could not tell from the paper what effect was occasioned by the injection of the serum. He did not think very favorably of sera, and said antidiphtheritic serum was the only one productive of much good.

Dr. Swinburne said that patients were free from pain in four days, and sometimes earlier if kept in bed, but his cases were all ambulatory.

Dr. Hugh H. Young of Baltimore said that it was probable that too little of the serum had been given. He suggested that larger doses should be given at once. The infection must be overpowered in the beginning to prevent further infection. He hoped that expectations regarding the efficacy of the serum would be fulfilled.

Dr. W. K. Otis thought these experiments a step in the right direction. He agreed with Dr. Young that larger and more frequent doses should be given at once.

Dr. Bransford Lewis of St. Louis took issue with Dr. Martin in regard to the inefficacy of sera in the treatment of disease. He had understood that the antitetanic serum had reduced the frequency of tetanus as well as its bad effects tremendously.

The Use of Ointments in the Urethra in the Treatment of Chronic Urethritis.—Dr. Hugh H. Young of Baltimore, after giving a brief history of the suggestions made during the past fifty years as to the value of medicated ointments in the treatment of chronic urethritis, showed an instrument which he had devised for depositing ointments in the urethra. The instrument which he had devised consisted of an outer tubular sheath somewhat more than a semicircle in extent. It was provided with a solid removable obturator corresponding to it in size. This was rotated in the outer sheath, and, when in a certain position, furnished a large trough to be filled with ointment. After filling the trough, rotation was continued until it furnished a closed, round instrument, the ointment being inside. After the instrument was inserted into the urethra, the obturator was rotated backward to its first position and the ointment was pushed out into the urethra. When the instrument was withdrawn the operator made pressure upon the glans and the meatus to prevent the ointment from escaping. The rapidity with which a large amount of sterile ointment could be introduced into the urethra, as well as the simplicity of the instrument, made it very satisfactory. It was a great convenience to have various ointments put up in collapsible tubes provided with long, nozzle-like attachments of metal, through which the ointment was deposited in a rope in the cavity of the instrument. The ointment could be sterilized by simply heating the nozzle.

Dr. Charles H. Chetwood of New York thought that there was no question but that there was a considerable number of cases of chronic urethritis that could be efficiently treated by the use of ointments and bougies. The objection to fluid applications was their uncertainty, but if they could be retained for a sufficient length of time their disadvantages were overcome. He had a little clutch, which fitted on the end of the penis, and this enabled the fluid to be retained two hours at a time, if necessary.

Dr. Bransford Lewis of St. Louis related his experience in making investigations regarding the use of ointment in these cases. He had used a hard rubber applicator, with a screw piston and soft rubber catheters, to make the introduction as easy as possible, and allow it to be retained.

He had experimented with lanolin and the other different bases as detailed. After two years his experience was so disappointing that he discontinued their use. He made use of an apparatus, a kind of sound which produced a massaging effect, with the application of the ointment.

Dr. Arthur T. Cabot of Boston thought the ointment treatment had been discarded long ago. He had used iodoform suppositories in certain cases, with an applicator left in the prostatic urethra. He had secured better results with aqueous solutions.

Dr. F. Tilden Brown of New York said that he was satisfied that there were certain cases of urethral disease that were benefited by medicaments with an ointment base. He related the various means that he had used in introducing the ointments. Finally he had used a preparation of a silver salt in lanolin ointment, from which he got firm adhesion to the sound of the ointment, which was not swept away by introduction into the meatus. He used some lubricant around the meatus. He was well impressed with the efficiency of this medication if it could be properly done. In chronic cases he thought a resolution of the strictures and a dissipation of the chronic discharges was brought about by a desquamation of the flat epithelium and a regenerative process.

The Surgical Treatment of Sterility in the Male.—Dr. Edward Martin of Philadelphia said that while sterility was sometimes the result of double epididymitis, this was the exception rather than the rule. However, there were a sufficient number of cases of sterility from this cause to justify an investigation and an effort to relieve the condition. It was with the general belief that the obliteration lay in the tail of the epididymis in conjunction with Drs. Carnet, Levi, and Pennington he had conducted experiments in order to determine the question as to whether or not by short-circuiting the vas and the head of the epididymis in cases of obliterating inflammation it might not be possible to provide a route by which the spermatozoa might escape. Dogs were used in the experiments, the vasa being ligated and cut on both sides a short distance from their epididymal origin. The proximal end was then split and sutured into an opening made into the head of the epididymis. A normal number of motile and seemingly healthy spermatozoa were observed. There seemed little tendency toward ultimate closure through cicatricial contraction. He did not have reliable evidence that these spermatozoa were fertile in dogs, and it might be that they underwent some developmental change in their passage through the epididymis. He related in detail the history of the first case operated upon.

Dr. Arthur Cabot of Boston considered Dr. Martin's paper an application of good common sense and good surgery.

Dr. Robert H. Greene of New York had seen a surgeon attempt to perform an operation of that type, and the difficulty was the small caliber of the vas. An attempt to inject fluid through the vas brought out the same difficulty.

Dr. Hugh H. Young of Baltimore had two cases of chronic prostatitis and seminal vesiculitis, with an obstruction at the epididymis, but they refused operation. He made pressure upon the seminal vesicles, and if the expressed fluid under the microscope showed large whorls of mucin, it could come from no other portion of the genitourinary tract except the seminal vesicles, and he felt certain that he had patent ejaculatory ducts. This would show that the obstruction was at the epididymis. The obstruction might be at the ampullæ, or higher up. He considered Dr. Martin's operation an advance in surgery.

Dr. Bransford Lewis of St. Louis said he did not consider himself a urethroscopist, but he had had two cases in which he could pass a soft, flexible sound, and catheterize the ejaculatory ducts and inject fluid into them as well, and that without any trouble and without inflammatory reaction. He used Swinburne's posterior urethroscope.

Dr. F. Tilden Brown of New York expressed himself as impressed with the value of this operation. In spite of Dr. Martin's statement that the operation was simple, he thought that it would be easy to make a failure of it. He had seen Dr. Martin perform the operation, and he felt that his timidity in undertaking it was fully justified. There were details in the technique, the bloodless approach to the vas, the necessity for special instruments, the placing of sutures for anastomoses, the snipping out of a piece of the epididymis, etc., which made him think that the operation could easily be bungled unless one had seen Dr. Martin do it. He thought it most desirable to find the point of occlusion, whether of the globus major or minor, or higher up.

Dr. Martin, in closing the discussion, said that he had not sounded the vas, because the operation being well started, this would only cause needless trauma, as there was no instrument small enough to go through the vas without traumatism. A proper diagnosis as to the cases suitable for the operation was important. It was possible that one might get some benefit from catheterizing the ejaculatory ducts.

Impressions of Genitourinary Work in Berlin.—Dr. H. H. Morton of New York related his experience of two months spent in the clinics of Berlin. He thought cases were more thoroughly studied, and reports and statistics more carefully kept, there than here. There were no snap diagnoses.

Second Day—Saturday, June 2.

Treatment of Prostatic Enlargement.—Dr. James Pedersen of New York said that his purpose in presenting this paper was to discuss what led up to prostatectomy, and what away from it. He considered the question as to when surgical intervention was advisable, and the operation of choice in a given case. In his opinion it was not possible to say categorically when surgical intervention should be advised until we had more detailed and searching statistics on both the radical and conservative sides of the question. He agreed with recent writers, who had entered a timely protest against excessive enthusiasm for operating, and there was a lack of anteoperation details. Whiteside, in 238 mixed cases, found really good results in only 30 per cent., a mortality in perineal prostatectomy of 20 per cent. in 36 cases reported by nine operators, a mortality of 8 per cent. in Murphy's 51 cases, of 5 per cent. in Young's 75 cases, and of 3 per cent. in Goodfellow's 75 cases. Five cases were reported in detail, as illustrative of points he wished to make.

Conservative Prostatectomy with Minimum Hazard.—Dr. Charles H. Chetwood of New York said that in presenting this communication it was not his object to set forth any novel technique, but simply to give the results of personal observation during the past year on a class of prostatic cases that were usually described as bad risks. As his results had been so strikingly satisfactory, he related the histories of these eight cases. He believed that had he not operated in two stages, most, if not all, would have succumbed. A summary of the cases showed that the ages of the patients were 80, 53, 79, 67, 69, 65, 70. The two in the neighborhood of 80 were very feeble, and were bad risks. There was evidence of advanced renal implication in one case. Three others were emergencies, having suffered for several days with acute retention. One of these had infiltration of urine into the prevesical region and two had intravesical hemorrhage. Three were more or less broken in health and neurotic. Complete radical removal of the prostate was done in all cases. Preliminary drainage was instituted in all but one case, where, on account of serious kidney complication, the galvanocautery technique was used. All up to the present time had done remarkably well. He laid particular stress upon the great value of formaldehyde gelatin as a local hemostatic. He had had

no serious hemorrhage since he had used it, and thought the postoperative conditions more comfortable. In employing the secondary operation, the parts, owing to circulatory decongestion and granulation, were much more accessible and the line of cleavage between the prostatic tissue and the capsular surroundings more easily separated. Hemorrhage was unimportant, shock trifling, the operative period minimized to a few minutes, and postoperative toxemia was almost entirely eliminated, as the patient during the postoperative period had become inured to his own secretions and his normal resistance fortified.

A Case of Stone in the Ureter, with Remarks on the Methods of Operating in Such Cases.—Dr. Paul Thorndike of Boston reported the case of a man who had had several mild attacks of renal colic within a period of two years, the pain on the right side extending from the kidney region to the penis. Physical examination revealed nothing. The *x*-ray revealed a stone, which was supposed to be in the bladder, but the searcher could not find it. A suprapubic operation was done, and a long probe was passed into the ureteral orifice on the right side and a stone contact was made. The stone was dislodged and the patient made an uneventful recovery. Seldom was stone found in this situation, the lower end of the ureter, without making known its presence by symptoms referable to the bladder.

Dr. Arthur T. Cabot of Boston said that he had always regarded the perineal route of performing prostatectomy as the safer, and was surprised at the statistics given. The death rate after perineal prostatectomy was 4 or 5 per cent. at the outside, while for suprapubic prostatectomy it was about 10 per cent. He considered the relief of small prostates through the perineal route a great triumph. He said that he understood that in the case of prostatism reported the patient was passing uric acid crystals, and that might account for the prostatic irritation. The preparation of the patient for prostatectomy was of the greatest importance. He mentioned several cases where preliminary drainage had brought about marked improvement and put the patient in condition for operation.

Dr. Hugh H. Young agreed with the reader of the paper that we were in need of carefully worked up statistics. He had just finished an analysis of 150 cases of prostatectomy, which would be published in the next volume of the Johns Hopkins Hospital reports, and these analyses were very voluminous. Last year's work showed only one death in a large number of cases, and that man had a badly infected kidney before operation, so that he had had practically no bad results from perineal prostatectomy so far as fatalities were concerned. Out of 164 patients that were using the catheter when they entered the hospital, only one was using it after operation. In 64 cases with complete retention of urine, there was not now one case of complete retention. He did not believe in paralysis of the bladder; he had seen so many cases with residual urine of over 1,000 c.c. that now had tonic bladders that he had dropped the term "paralysis of the bladder" from his vocabulary. Of 145 cases of hypertrophy of the prostate that could be called benign, only 5 could be said to have given imperfect results. Most of these had the small cirrhotic fibrous prostate. The bad results were because he did not appreciate enough the cicatricial contraction at the prostatic obstruction. The claim could be made that through the perineal route all of the obstruction could be removed absolutely. He did not consider it just to blame perineal fistula on the perineal prostatectomy. In the past two years he had 102 cases, and only four cases of perineal fistula followed, and two of those were quite recent, and would probably heal.

Dr. Edward Martin of Philadelphia said that he had had some success in using dilators in the case of small prostates with contracted ring. He had obtained complete relief by dilating this contracture. There was but little bleeding, and the relief lasted for months.

Dr. George K. Swinburne of New York said that in considering the statistics of the results of operation it should be borne in mind that there were a large number of cases which could not, or would not, be operated upon. He had a patient who had used a catheter for twenty years. The history of this case was given, showing how prostatectomy had been avoided and the man kept comfortable by draining the bladder and performing a suprapubic cystotomy.

Dr. Bransford Lewis of St. Louis thought the conservatism of both papers was highly commendable. He referred to the use of the retained catheter instead of the boutonnière; in his experience this had been of great value. Bladder drainage would not suffice in cases of calculi. Here it was proper to give some preparatory treatment; then, under local anesthesia, the bladder could be opened and the calculi taken out. He cited two cases in which he had followed this plan.

Dr. L. Bolton Bangs of New York thought the important question was not what operation to choose, but whether to operate or not. We should not decide to operate because a man had retention of urine, with possibly a slight enlargement of the prostate. Of late a great many people had been preserved from radical operation, and he thought the desire of the laity to be operated upon was less than formerly. He was a believer in the preparatory care of patients before operation. He had resorted to perineal drainage only in exceptional cases. In opening the bladder, where obstructive symptoms were present, he had made it a rule to place his finger in to determine whether there was any fibrous exudate that produced obstruction. He sometimes dilated these with the forceps, and sometimes with the fingers, and this occasionally gave relief.

Dr. Pedersen said that in regard to Dr. Cabot's criticism of the death rate, as he had reported it, he would say that his paper had aimed to take an analysis of the average results as found in reports coming in to him. Therefore, the death rate of certain operators was better than the average. It was important that we should know definitely the end results of these operations; we should know about the sexual function, the bladder function, etc. It was undoubtedly true that crystals in the urine would account for symptoms of prostatism. In regard to the question of rectal fistula, he said that the reports were those of Albarran; that in this country we saw few fistulas due to prostatectomy in the hands of competent men.

Dr. Chetwood said that he did not want to be understood as favoring long drainage or as recommending proceeding with enucleation and other procedures without using the catheter. He did not think the catheter was able to do what perineal drainage would.

Does Syphilis in Some Cases Spontaneously Abort in the Primary Stage?—Dr. R. W. Taylor of New York said that he had for a number of years been making a study of this question. It was one of the canons of medical belief that a chancre was always followed by general syphilis. A review of statistics showed that out of 1,291 cases of general syphilis a chancre had preceded in all but 22. He had become convinced that spontaneous abortion of syphilis in the primary state did sometimes occur. He reported four cases in detail which had occurred in his experience, in which the patients had undoubtedly Hunterian chancres, and yet who never developed general syphilis. In these cases he was very sure that there was no previous history of acquired or hereditary syphilis. He had noted altogether ten cases reported by seven observers. Burnett thought it altogether possible that these sores were typical chancres, and through some influence modifying the virus the disease was checked in the primary stage. He was of the opinion that some of the cases reported as successful excision of chancres were instances where the disease had aborted in the first stage. In the study of such cases we should acquaint ourselves

as far as possible with the patient's history and with that of his immediate progenitors. An antecedent-acquired syphilis might be followed by chancriform-relapsing lesions which might mislead the observer. While hereditary syphilis might confer, and usually did confer, immunity on its bearer, it was possible for the hereditary disease to wane, and immunity to be lost.

A Case of Hereditary Syphilis.—Dr. Taylor also reported this case. He said that a man of thirty years had presented himself with syphilis, and when told what ailed him, said that no doubt his wife was also infected, as she had a sore on the vulva and a generalized rash. She was in the eighth month of her first pregnancy, and had probably been infected when about five and one-half months pregnant. Neither parties took any true antisyphilitic treatment. An apparently healthy male child was born at term, and was scrupulously watched for months, but nothing abnormal was found. The child had but little antisyphilitic treatment, as the parents were not particularly careful on this point. The child grew apparently normally, but the second teeth were of the Hutchinson type. At the age of four years periostitis of the right humerus and synovitis of the right knee developed. Under mixed treatment and the local use of mercurial ointment the pains ceased, the articular lesions subsided, and the child entered into very satisfactory health. This case, though unusual, was explicable in the light of the fact that it was now conceded that there was a virulent form of hereditary syphilis, in which the old-time classic features were marked, and there was a dystrophic form, in which there was slight ill health at times, scarcely appreciable, and yet dystrophic changes in the bones, teeth, ears, eyes, brain, etc., might occur.

Dr. Wood Ruggles of Rochester, N. Y., related the instance of a man forty-five years old, who had had as characteristic a chancre as he had ever seen. He had pronounced adenopathy in both groins. No roseola had appeared up to four and one-half months after the infection occurred.

Dr. Edwin C. Burnett of St. Louis, whose patient Dr. Taylor referred to in his paper, said he had been able to hear from him for the past seventeen years, and he was hale and hearty and the father of perfectly healthy children.

Dr. N. B. Carson of St. Louis thought that before arriving at definite conclusions we should investigate the source of infection, and see if the case really was one of syphilis, as sores upon and about the genitals often closely resembled chancres.

Dr. George K. Swinburne of New York said that when he had been interne at St. Luke's Hospital he had seen many cases that passed as true chancres which were followed by no secondary sequelæ except the adenopathy. He knew of a case where chancre was apparently not followed by secondary symptoms. Seven years later one side of this man's body became paralyzed, and he was placed under mercurial treatment. He partially recovered, and six months later the same thing occurred to the other side of his body, and he partially recovered from that also. This man evidently had syphilitic lesions late.

Dr. James Pedersen of New York cited two cases, in which Dr. Bangs had concurred with him in diagnosis, and which seemed to have developed no secondaries. He agreed with Dr. Taylor that there was a spontaneous resolution or cure in each case.

Dr. A. C. Wood of Philadelphia said the question arose whether or not the child was refractory to the poison of syphilis, and also had these patients inherited sufficient of the poison to render them immune, and yet not enough to show during life.

Cyst of the Prostate.—Dr. Arthur Tracy Cabot of Boston presented this paper. He classified this rare condition as follows: (1) Echinococcus cysts, of which Belfield had found but three authentic instances originating in the prostate. (2) Retention cysts due to distention of the occluded prostatic glands. (3) Cystic dilatation of the utricle, a condition occasionally found in children. (4) Cysts or cystic cavities might form in connection with cancer of the prostate. He reported a case belonging to class 4. An operation was performed through the rectum for a prostatic swelling simulating an abscess. As the patient succumbed to a pyelonephritis, an autopsy was possible, which revealed a cancer of the prostate in an early stage. The second case reported was probably one of retention cyst. The patient recovered, so the pathology could not be studied. In this case cystoscopic examination showed projections from the prostate to the left and behind the urethral orifice. A projecting tumor on the left side of the internal meatus had a translucent appearance, with few vessels on its surface. On opening the bladder this tumor was found to be about the size of a cherry, projecting well into the bladder and against the urethra, which it tightly closed. When it was seized by the forceps it collapsed. The wall of the cyst was cut away and the interior seared with the paquelin cautery. The fluid was lost. This patient made a good recovery. He thought this case could have been dealt with through the urethra with a Bottini cautery. Such cysts were extremely rare, though cystic dilatations of these glands of insignificant size were of common occurrence in old prostates.

Dr. Robert H. Greene of New York referred to the extensive pathological work done by Dr. Harlow Brooks and himself in their endeavors to find a cause for prostatic hypertrophy; in this work they ran across several cases of retention cysts, and he believed the same process was at work in these various conditions met with clinically in the prostate.

Some Remarks on Litholapaxy.—Dr. W. K. Otis of New York made this contribution, illustrating his remarks with blackboard demonstrations. He also presented many instruments.

A Case of Litholapaxy.—Dr. Edward L. Keyes reported this case. The man, forty-five years of age, gave a history of syphilis twenty years before. Dr. Van Buren had diagnosed the case as locomotor ataxia, and Dr. E. L. Keyes, Sr., had confirmed the diagnosis. Mixed treatment was pushed for a while. He used a catheter once a week, but did not irrigate or inject anything into the bladder. The urine gave no evidence of neoplasm. It was acid purulent brothy, and had a specific gravity of 1022. The pneumaturia ceased, and there was some grit passed from the urethra. He began to have pain in the region of the left kidney. In 1895, when he reached complete retention, a litholapaxy was performed, and a uric acid stone, with a phosphatic covering, about the size of a pigeon's egg, was removed. More phosphates were crushed six months later. In 1897 eight more phosphatic stones were crushed and washed out, and in 1898, six more. In 1900 a one and-a-half dram stone was washed away. In 1904 the *x*-ray showed tuberculosis of the body of the last dorsal vertebra. This was the cause of the so-called ataxia. In 1905 he passed a small stone through his catheter, and in March, 1906, 158 stones were washed away in twenty minutes without crushing. Their total weight was two drams. At the end of twenty-four hours the patient was apparently as well as ever. This case was the third in which he had known a competent *x*-ray man to overlook stones in the bladder.

Dr. Arthur T. Cabot of Boston reported a case of multiple calculi occurring in a man upon whom he operated several times, removing a large number of stones. On account of this tendency to stone formation or reproduction, he was advised to have his bladder washed out once a fortnight with good results.

Dr. F. Tilden Brown of New York said that with the knowledge that the stones were urate of soda or urates mixed, it was fair to presume the *x*-ray would show

nothing. He reported the case of a patient with a pure uric acid stone; excellent plates were obtained by Mr. Caldwell, but they portrayed nothing.

Some Cases of Kidney and Ureteral Stone.—Dr. George K. Swinburne of New York reported these cases. In Case I. he suspected stone of the right kidney. Cystoscopic examinations revealed nothing, and an *x*-ray picture was likewise negative. At operation a small, irregular calculus of lime was found in the extreme upper pole of the kidney and removed. Several attacks of oxaluria followed, which were always cleared up by dilute nitrohydrochloric acid. In Case II. examination showed a perfectly normal bladder and the mouths of both ureters perfectly normal in appearance. The posterior urethra was somewhat congested, and there was a slight nodule in the epididymis on the right side. About a year later this case was operated upon for stone in the kidney, and some time later cystoscopic examination showed involvement of the mouth of the right ureter. The calculus was removed extraperitoneally, and was a large oxylate of lime stone. This patient also had several postoperative attacks, probably due to oxyuria. Case III. was one of stone of the kidney, as shown by the *x*-ray. Case IV. was also one of renal calculus, revealed by the *x*-ray. In Case V. the patient had been under treatment for some time; the *x*-ray and cystoscope failed to reveal anything. Finally, after an exceedingly acute attack of pain, cystoscopic examination under ether showed the right uretheral orifice contracted on the face of a projection as if it were pushed forward, there being a pocket to the inner lower side formed by the projecting bladder wall with the intramural portion of the ureter. He thought there was a stone lodged in the lower end of the ureter; the *x*-ray picture showed three small shadows in the region of the left ureter. An unusually difficult exploratory suprapubic cystotomy was performed. The conditions were found exactly as in the cystoscopic examination, but no calculus could be found. The ureteral orifice was so contracted that nothing could be made to enter. A fine probe always impinged at the orifice, the bladder wall would yield, and the urine could be seen welling up from the orifice. There was a pouch to the inner side of the ureteral orifice fully an inch deep, running under the ureter as it passed through the wall. A thick cicatricial band could be felt curving upward and inward, due to inflammatory infiltration or to continued muscular spasm. As there seemed no prospect of accomplishing anything, the wound was closed, leaving a suprapubic tube for drainage.

The Diagnosis of Renal Colic.—Dr. Edward L. Keyes, Jr., of New York did not discuss the familiar phenomena of renal colic, but endeavored to show that, though renal colic was the cardinal symptom of renal stone, severe and typical colic might occur from other causes. These causes might usually be distinguished by the means ordinarily at hand. The locality of the pain usually pointed to that of the stone. It also occurred on the same side as the affected kidney. He had known cases where the presence of frequent and painful urination was the only symptom of renal stone. During the past few years he had come in contact with a number of patients in whom other conditions—genital, urinary, intestinal, etc., produced symptoms suggestive of renal colic. He related the history of one case, in which the renal colic was evidently due to gouty disposition, while in some cases it seemed that showers of crystals were caused by digestive crises. He cited a case where proper diet and hygienic conditions had relieved a patient of attacks that had persisted from childhood. There were some cases entirely due to intestinal derangement without any disorder of the urinary organs. He reported a case in which the renal colic was due to prostatitis and vesiculitis, and one neurotic case which began as a pyelonephritis and wound up in a series of neurotic disturbances. No attempt had been made to cover every possible condition that might cause renal colic. As the gall-bladder cases were not confusing he had not spoken of them.

Dr. Bransford Lewis of St. Louis said that he had learned not to depend upon the *x*-ray for diagnosis, whether the results were positive or negative. He reported a case in which there were three ureters, giving three urines; the ureter on the right side was normally situated, while the two ureters on the left side ran to the two poles of one kidney. One ureter was infected with gonorrhea, while, strange as it may seem, the others were not.

Dr. Francis R. Hagner of Washington reported the case of a young man who relieved his colicky pain by placing his buttocks on the bed and his head on the floor, and then taking deep inspirations. Following this relief there would be a copious flow of urine. This patient had a chronic seminal vesiculitis on both sides, a chronic prostatitis, with the prostatic fluid filled with pus. An oxalic stone was revealed by the *x*-ray and removed successfully. Ureteral catheterization was tried in this case, but failed to reveal the stone.

Dr. Arthur T. Cabot of Boston reported two cases in which the diagnosis rested between ureteral stone, ureteral hemorrhage, and appendicitis. He also presented the largest stone he ever saw removed from the lower end of the ureter; it weighed 190 grains, and was found from one to one and a half inches above the bladder in a woman. He said he had ten cases of ureteral stone, and eight of them were operated upon, some per vaginam.

Dr. George K. Swinburne of New York reported cases showing that external manipulation would often cause contraction of the ureters and the passage of ureteral stones. Firm manipulation over the loins and side, if a reasonable amount of delay was permitted, would often cause the passage of ureteral stones.

Dr. Bransford Lewis of St. Louis said that when calculi were situated at the lower end of the ureter he could, through the operative cystoscope, introduce a dilator, dilate the lower end to two or three times its caliber, and remove the stone with a specially devised forceps.

Officers Elected.— *President*, Dr. W. K. Otis of New York; *Vice-President*, Dr. Harvey G. Mudd of St. Louis; *Secretary*, Dr. John Van der Poel of New York; *Member of Council*, Dr. Hugh H. Young of Baltimore.

Habitual Constipation in Children.—Luigi Concetti divides the forms of constipation into three groups according to their etiology, the alimentary, functional, and anatomical, and says that the proper treatment is the finding and removal of the cause, using at the same time whatever palliative treatment is indicated by the symptoms. Enemata he uses only temporarily, with glycerine or soap, to soften deposits in the rectum and lower bowel. Massage and laxatives, with proper diet, are most useful. The alimentary form may arise from deficiency in quantity or quality of nutrition, from vomiting, or from too rich food. The remedy is the change of nurse, or such treatment of the mother as to make her milk suitable, or the addition of mixed feeding. Vomiting may be combated by change of food or of nurse. When resulting from spasmodic stricture of the pylorus, vomiting must be treated by relieving the intestinal catarrh that causes the spasm. If the stenosis is organic treatment is of little avail. Functional constipation results from atony of the intestine, and follows inflammation of intestine or peritoneum, cerebral disease, or bad nervous condition. Easily assimilable food should be used, massage and electricity, enzymes to increase digestive activity, and regular habit of defecation be encouraged. The anatomical form arises from congenital malformation, stricture, tumor, too long, or abnormally large intestine, or colon, or fissure of the rectum. Such forms may require surgical interference.—*Rivista Critica di Clinica Pediatrica.*

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Virginia.—At the June examination there were one hundred and seventy-nine applicants. Of this number one hundred and four passed the examination, twenty-four failed, forty-seven took only a partial examination, and four withdrew from the contest. At this meeting it was agreed by the Medical Examining Board of Virginia to enter into reciprocity with the Regular State Board of Examiners of Georgia.

North Dakota.—Upon licenses upon examination, and bearing date of July 1, 1905, or later, North Dakota reciprocates with the following States: Maine, Vermont, Michigan, Illinois, Wisconsin, Iowa, and Wyoming.

Indiana.—The Supreme Court of this State holds that the State Board of Medical Examiners is within its rights in revoking a license for gross immorality.

California.—Among the rules adopted by the State Board of Medical Examiners, in August, provision is made for other than the ordinary test by printed questions. Thus there may be identification of microscopical or gross pathological preparations, clinical examination of patients, or any other practical work. But in all such cases the questions must be answered in writing, in order that the identity of the applicant may not be revealed to the examiner. In order to pass, in the State of California, applicants must obtain an average of at least 75 per cent., and must not fall below 60 per cent. on any one subject.

New York.—In an article on "Reciprocity in Medical Licensure" in the *New York Medical Journal* of October 13, 1906, Dr. Albert Vander Veer claims that "it can be said without fear of successful contradiction that to-day the New York statutory requirement for admission to the practice of medicine is clearly equal to the highest required by any State or Government in the civilized world."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 13, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	390	160
Diphtheria	205	22
Measles	50	2
Scarlet Fever	73	1
Smallpox	—	—
Varicella	9	—
Typhoid Fever	113	15
Whooping Cough	33	11
Cerebrospinal Meningitis	5	4
Malarial Fever	.....	.....
Totals	878	224

Intermittent Claudication, with Report of a Case.—Johann Flinterman presents the history of this interesting case. The patient is a married man forty-one years old, a native of Polish Russia. For years he has complained of weakness and pain in the lower extremities, first in the left and then in the right. These symptoms were not constant, but were most marked after overexertion, either standing or walking. After rest they would disappear for quite a while, only to appear again after overexertion. Finally, however, the intervals between them having become shorter and shorter, the pain and weakness became constant, even when the patient was resting. There were signs of imperfect nutrition of the parts, the foot becoming stiff and cold. Signs of insufficient blood supply were manifested. Impairment of motion and sensation became very intense. Finally gangrene appeared at the most peripheral parts. A condition developed showing a change in the blood vessels, such that pulsation could not be felt in some of the main arteries of the extremities. The patient at an early age was exposed to changes in temperature and to overexertion. He had early begun the use of alcoholic stimulants and tobacco. After amputation, examination of the blood-vessels showed an endarteritis obliterans. The writer believes that the disease is after all not so very rare.—*Detroit Medical Journal*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending October 13, 1906:

HOSPITAL REFORM IN A NEW LIGHT.*

BY HENRY S. STARK, A.M., M.D.,

NEW YORK.

THE trend of current medical events indicates very plainly that the next few years will witness a new era in hospital management through the introduction of certain innovations which will make the old régime look like ancient history. The illuminating papers read last winter at the medical societies, and the lively discussion they elicited, which later found its way into the columns of the lay press, bore eloquent testimony to the dissatisfaction that exists in the profession and among the laity with the management and the administration of our hospitals. These articles foreshadowed certain changes, which are now in their incipient stage, but which are bound to be inaugurated in the near future.

The wastefulness, the yearly deficits exhibited in the financial statements, the extravagant architecture which drains the sinking funds, the cry of "no room," the tendency on the part of a few men in the profession to arrogate to themselves so many prerogatives connected with their positions, as virtually to make these institutions their branch offices, so to speak, and thus to create a "medical trust." These were some of the facts brought to light in the discussions of last winter.

Already the medical and lay boards have certain reforms under serious consideration by virtue of which old traditions will be wiped out and be replaced by methods inspired by the modern spirit of research, and which are intended to adapt themselves to the constantly varying phases of modern society, and to this age of progress and broader thought. And I am not treading on doubtful ground when I venture the prediction that if the pace set be maintained there is no telling to what bounds this radicalism is destined to reach, nor can we predict how far-reaching its influence will be on medical education and medical schools.

Although, unfortunately, this movement for hospital reform has been allowed to smolder, nevertheless public sentiment is overwhelmingly in its favor to-day; it is a vital issue in medical thought and is bound to bear results once the public becomes acquainted with the different phases of hospital management, and with the weak points of the system.

At the outset I wish it to be understood that I am not arraigning our hospital system, nor do I wish to convey the impression that neither progress nor improvement has been made within recent years. I frankly acknowledge that many reforms have been instituted lately, and I know of still others that are in contemplation or in progress. What I allude to is the fact that under existing conditions the greatest efficiency of service is not assured, nor are the many services that a hospital can render to the public, and to the medical profession, available as matters stand to-day.

In many respects hospitals are conducted on the medieval lines laid out when they first were created, and thus their sphere of usefulness has not continuously improved in order to meet exigencies of modern industrial and social life. For convenience of this paper, I have made the following classification of hospitals: Firstly, a class having formal denominational connections, or which require their governing bodies to belong to a specified denomination or nationality; secondly, hospitals controlled and supported by the state or municipality; thirdly, hospitals connected with medical seats of learning; fourthly, hospitals whose governing bodies are non-sectarian and are supported by voluntary contributions, and fifthly, a number of institutions of an eleemosynary character, which fall below the modern standard of what hospitals should be and are therefore not considered in this paper.

A word concerning the third class, namely, hospitals connected with medical schools. It is very apparent that such institutions are to all intents not primarily places for the healing of the sick, but are subsidiary instruments for medical education and clinical instruction. One of the functions of such a hospital is to furnish material and subject for study both for the matriculants and the members of the faculty. Of necessity such hospitals must first consult the interests of the student-body rather than that of the indigent sick, for it is upon the revenue derived from the former that the life of the institution depends. Thus we have a type of hospital which savors more of commercialism than of humanitarianism, and therefore it becomes a question of economic and civic interest whether such hospitals are properly entitled to municipal support. In this city we have several notable examples of such institutions, and it is a well-known fact that for a number of years, whenever the city's budget was made up, they found it necessary to have representatives appear before the Board of Estimate and Apportionment to oppose the sentiment against their securing a share of the city's bounty.

On the part of these "college hospitals" it was claimed that they provided and cared for a quota of the indigent sick of this city, and consequently were entitled to a certain appropriation. On the other side, it was argued that while these hospitals did treat some of the city's poor, it was done not from purely charitable motives, or from an unselfish disinterestedness, but it was a question of personal gain and aggrandizement. These institutions furnish facilities for the reception of

*Read at the September meeting of the Metropolitan Medical Society.

a limited number of patients who are able to make compensation for the treatment they receive; but the revenue thus derived is not appropriated, as far as I know, for the general uses of the hospital, that is for the relief of the sufferings of that class which is admitted free, but it finds its way into private channels. Such hospitals partake, in this respect at least, more of the nature of private or pay hospitals for the physicians connected with them, who contribute nothing of the incomes derived from them towards the maintenance of the hospital. Here we have the unique spectacle of a private hospital, which yields a handsome revenue to the members of the faculty, asking for an annual appropriation to help maintain it, when in reality its main purpose is intended as a clinical feeder for the students and to furnish material for operating and demonstrating.

Regarding hospitals supported by the city or State, it is to be noted that these institutions may be made more useful in many ways. The treatment of the sick poor should not claim their attentions alone. They should become centers for the medical education of the masses, where the people could receive instruction in the rules which govern health and prevent disease. The hospital should be made an auxiliary to the schoolhouse; in the former the care of the body should receive attention just as in the latter the training of the mind, does. The services rendered to the public by an up-to-date hospital should no longer be summed up in the mere statement that it administers to the sick of the community; the modern hospital can be made to have a larger range of usefulness, and thus render a greater service by providing opportunities for instructing the masses in the laws governing health, in sanitary living and in the prophylaxis of disease. I therefore make the suggestion to the metropolitan hospital boards and to our municipal authorities that a modest beginning be made on the lines here indicated; that provision be made for delivering lectures at one of our larger hospitals during the winter months on questions relating to the prevention of disease, and conducted in such wise as not to interfere with the general routine work of the hospital. I am confident that this innovation would be hailed with such satisfaction as to rival in popularity the lectures held under the auspices of the Board of Education. In our own city and elsewhere there are no opportunities offered to the people for such a practical and necessary education, although the need of it is nowhere so imperative as it is among the members of the younger generation, who are growing into manhood and womanhood, ignorant of the dangers that menace their future health and happiness. As an object lesson in the prevention of communicable diseases this feature would prove a great blessing. It certainly is a misfortune that our schools and universities should be so woefully incompetent to supply such a need. Such lectures might be delivered under the auspices of a hospital by selected members of the medical staff, but not necessarily within the hospital itself.

The utilization of hospital facilities for purposes of instruction could be advantageously extended by appointing to the house staffs a larger proportion of graduates than is now the rule. A study made by me of the number of graduates in 1906 of the leading medical schools in New York shows that about 30 per cent. secured hospital appointments in large general hospitals. Of the remainder about 50 per cent. secured positions in minor institutions in which, however, the facilities for obtaining a practical knowledge are so inferior as scarcely to compensate a beginner accepting an interneship of a few years. It appears, therefore, that about 50 per cent. of medical graduates are not sufficiently equipped to practise their calling conscientiously and with justice to their clientele. And yet the clinical facilities in this city are well-nigh inexhaustible.

There are in the Boroughs of Manhattan and the Bronx, all told, about sixty hospitals, of which about one-half are devoted to the treatment of general diseases, the other half to the treatment of special diseases and conditions. Of the general hospitals, about seventeen have a capacity of over one hundred beds, and approximately there are about six thousand free beds in these institutions. A study of these figures in connection with the number of semi-annual appointments made on the house staffs, makes it very evident that in many of the general hospitals, the number on these staffs could be materially and profitably increased, and thus suitable provision could be made for a larger number of our medical graduates. My figures make it evident that this increase could be carried out without impairing the service. All that is required is to make suitable house provision for such an augmented staff and to reapportion the inmates accordingly. True the economies of the hospital would suffer, but then retrenchments could be easily enforced in other directions whereby the balance sheet would not show a deficit. A hospital with a capacity of two hundred beds, could be made to accommodate a house staff of eight to ten, one with a capacity of three hundred beds could accommodate ten or twelve graduates. A fair ratio would be about one physician to twenty-five patients.

Arguing in the same vein, the staff of visiting physicians could be likewise augmented without detriment to the hospital management or service. The antiquated policy to which our hospitals so religiously adhere, of centralizing the medical and surgical work in the hands of a few should be brushed aside. There is no justification in theory or in practice of restricting the services of a hospital to a selected few to the detriment of the many who are in need and deserving of such appointments and who represent the highest type of physician. Bearing in mind that these positions are numerically limited, while the aggregate of practitioners is an increasing quantity, it would, it seems to me, appear to be the part of wisdom to regulate the number of visiting physicians according to the number of patients. Thus in a hospital whose capacity is two hundred beds, in place of a visiting staff of three physicians, the number could well be increased to five. Such a change would mean that a larger proportion of practising physicians would enjoy the prerogatives and emoluments that are a natural condition of such positions, and it would be a severe blow to the present tendency of centralizing hospital appointments in the hands of a few. The economic principle involved would be that of the greatest good to the greatest many.

According to the latest edition of the Medical Directory there are about forty-four hundred practising physicians in the Borough of Manhattan and the Bronx. Of this number about five hundred (500) hold hospital positions. These

positions are scattered among sixty hospitals of a capacity of seventy-five beds and over; in other words only about 10 per cent. of practising physicians hold appointments on the staffs of large hospitals. The rest are entirely excluded without rhyme or reason from hospital practice, and cannot enjoy even a share of the benefits derived from such a connection. If you will take the trouble to look through the pages of the Medical Directory you will also note that a number of physicians are credited with appointments in four or five hospitals and that still others hold two different positions in one hospital, to the exclusion of reputable and deserving physicians who are clamoring for hospital appointments. The system which tolerates such an unjust discrimination certainly needs modification, and a more equitable adjustment, especially when we take into consideration that without a hospital connection, a physician is seriously handicapped in the pursuit of his calling in a city where people flock to the hospitals for treatment.

In place, therefore, of an exclusive and restricted attending staff, appointments should be made on a more liberal scale, so that the vast majority of physicians would feel that they were not discriminated against by a small but influential minority of their own brethren. In order to carry out more effectively the plan I have outlined the suggestion might be also adopted of retiring from active service all such members of an attending staff who have served continuously in one capacity a specified number of years, say twenty or twenty-five years. The practice of enforced retirement after a long service or for advancing age, is not unfamiliar to you in other walks of life and in other professions. It is based on sound judgment, while the wisdom of it is unquestioned. It is not unreasonable to be required to sever an active connection from a hospital if for no other reason than that of allowing another the same opportunities. Such retirement from active participation of the service would not necessarily mean that the retired attending physician should be deprived of certain well-deserved privileges. On the contrary, such physicians should be retained in an advisory or consulting capacity, with authority to treat pay patients.

In entering on a campaign for improvement in hospital management, the necessity for reforms other than those suggested soon manifest themselves; but the one which overshadows all others in its significance to the public and to the profession is the practice that prevails in our hospitals by which only the appointed visiting staff is permitted to make use of the operating room and of the beds in the pay wards for their private patients, and which arbitrarily denies such privileges to all other unassociated physicians. This deplorable state of affairs with but few exceptions exists in every hospital in New York where there are pay wards. No matter how capable and reputable a physician may be, and no matter how desirous a patient may be to retain the services of his own physician, directly the latter is admitted to a hospital, his own physician's connection with the case is brought abruptly to an end, while the patient is forced to accept the services of the attached physician, and in many instances one not of his own choice, or else be denied admission. This is a fact with which the public is not generally acquainted; most people being under the impression that any physician in good standing is authorized to take his private patients into the pay wards, but are chagrined on learning that the doors of the hospital are closed to their family physician, because he is not fortunate enough to be officially connected with the institution. Considering that hospital positions are few and far between, and that in not a few instances they are the result of influence rather than of individual worth or personal merit, it is not difficult to understand that it is only a question of time when there will be developed a "system" as baneful to the mass of physicians as it is profitable to the elect of the profession. The tendency to the creation of such a system is greatly promoted nowadays by the desire of patients to seek hospital treatment in preference to being treated at their homes in severe or prolonged illness. It is matter of everyday experience with physicians to see more and more of their cases enter hospital wards. Private rooms and pay wards are a comparatively new feature of hospital life, and it is a moot question whether the founders of our great institutions of healing ever contemplated any such innovation or misapprehension of their original plans.

It would seem that a hospital which was designed to meet the want of the indigent sick would enlist every inch of ground and every bed to the charitable purposes for which it was created, instead, as now obtains, of entering the commercial arena and making a bid for patients. But conditions of life are such to-day that private rooms seem to be a public necessity. The medical and surgical requirements in these advanced days of the medical sciences for ministering to the sick are on such a prodigal scale that home treatment is unfeasible in many cases and in others impossible of being properly carried out. The elaborate paraphernalia of the operating room, the array of surgical appurtenances, the need for trained assistance, all combine to give an impetus to this method of handling patients. These circumstances have given rise to a "system," the importance of which cannot be dismissed without serious consideration of the consequences involved. A grave problem has arisen of far-reaching interest to the medical man, which he must approach with deep concern. On the one hand we have a public educated to avail itself of the facilities of a hospital in severe illness, and on the other hand a cast-iron regulation which closes the doors of the hospital to the majority of practitioners. This "system" has made such striking inroads on the earning capacity of physicians in cities where it flourishes as to entail enormous pecuniary losses. It seems like an unfair and anomalous proposition that a minority of physicians should claim, as though it were a property right, the privileges that rightfully belong to the whole community of physicians.

To give you an idea to what extent this system prevails, I submit the following table of figures collected by myself. The institutions cited are among the largest general hospitals in this city:

Hospital.	Free beds.	Pay beds.
Presbyterian	197	23
St. Vincent's	250	125
St. Luke's (new pavilion)	250	65
Mount Sinai	350	73
German	200	45

Roosevelt	205	39
New York....	Seventy per cent. of patients treated were free patients; new pavilion for pay patients is soon to be opened.	

A study of these figures makes it appear that in the aggregate about 25 per cent. of the beds in our large hospitals are at the disposal only of pay patients for whose purposes large pavilions are maintained, and from which unattached physicians are barred. Notable exceptions to this rule are the following:

In the German Hospital, ex-internes and members of the dispensary staff of ten years' standing may treat pay patients. In Mount Sinai Hospital chiefs of the dispensary staffs of ten years' standing may treat pay patients. In the New York Hospital, a specially selected list of thirty physicians not attached to the regular staff may operate at the hospital.

The private pavilion is partly designed to produce an income which is employed to make up the yearly deficit incurred in the maintenance of the free beds. Now it would seem from a purely business viewpoint that it should make little difference to the managing boards from what class of physicians that revenue is derived, providing the latter are men of acknowledged standing in the community. This much is morally sure, the gross receipts would be materially enhanced while there would be fewer vacant beds.

This very matter was advocated by me as long as ten years ago, in an article which appeared in the MEDICAL RECORD January 25, 1896, entitled "Should Our Hospitals Extend Their Facilities for Operating to Physicians Generally?" I then took the ground that the managers of our hospitals should grant certain physicians who are known to them to be capable and well qualified, the privilege of operating upon their pay patients in the hospital under certain restrictions and limitations. What these restrictions and limitations were, each hospital must determine for itself and work out according to the character of the institution, and the nature of the cases that are eligible for admission. It was not contemplated that all physicians, promiscuously, would come within the scope of this concession, but only a certain quota selected according to rules, which each hospital would make for the protection of its own interests. I argued that physicians were greatly hampered in the practice of their calling by the oppressive and archaic rule which closes the doors against them. It was shown that on account of this drawback, physicians were constantly losing their most lucrative cases. I recommended that one or more of our more liberal institutions should take the initiative of abolishing this practice. It was not long after the publication of my paper that the question was favorably taken up by several institutions in this city with satisfactory results. Among the remoter results, auxiliary operating rooms became the vogue, and today no hospital is considered fully equipped without them; the number on the house staffs was of necessity increased, and this increase has proven a great boon to our young graduates. To-day hospitals are conducted in many cities along the lines here suggested, with great satisfaction to all concerned. Thus the patient has the choice of hospital or home treatment; the well-grounded feeling of hostility of the profession against hospitals gave way to one of friendly disposition; further, there were found to be fewer empty beds in the pay wards, and in consequence appeals for financial support became less peremptory, and finally, there was not that tendency to pauperize a susceptible public by crowding the free wards with patients who could pay for medical services.

I believe some of the measures recommended in this paper will be adopted in the near future, and that in a certain sense the superiority of one hospital over another as a public benefaction will be determined by its disposition to follow the spirit of the times, and submit graciously to the popular demand for an "Open door."

CHOICE OF COW'S MILK.

BY J. ALLEN GILBERT, PH.D., M.D.,

PORTLAND, OREGON.

No article of diet is so universally used by man and beast as milk, and any information which will in any way aid in the intelligent choice and use of so useful a commodity must necessarily appeal to the interest of one and all.

I shall deal with the subject in two general heads, viz., first, a consideration of fifteen qualities considered by the writer to be desirable in a milk to be used as human food—infants and invalids being specially in mind—and, second, a comparison of the main breeds of dairy cows with a view to selecting the breed best adapted to fill these requirements. No attempt will be made to deal with rules governing the modification of cow's milk for the purpose of infant and invalid feeding. The sole purpose will be a choice of milk.

QUALITIES OF A GOOD MILK.

(1) *High Percentage of Solids.*—To the average individual milk is milk, and the consumer receives and pays for his milk by the quart with practically no knowledge of the food content of the milk he purchases. The milk of all animals, as well as of individuals of a certain species, varies markedly in the quantity of the respective ingredients contained therein. In stating the composition of "cow's milk" considerable variation must be allowed, depending upon the breed, individual cow, environment, exercise, food, etc., as will be shown by the following table:

TABLE I.[16]

	Maximum	American Average	Minimum
Water	90.69	87.17	80.32
Fat	6.47	3.69	1.67
Casein	4.23	3.02	1.79
Albumin	1.44	.53	.25
Sugar	6.03	4.88	2.11
Ash	1.21	.71	.35

Thus it would be possible for one man to pay two or three times as much for food content in milk as some more fortunate consumer whose milk contained a large percentage of solids. However, in such calculations quantity of solids is not the only desideratum. Milk has quality as well as quantity of solids, and often for purposes of food for invalids and children the former is the more important, as we shall see later.

The quantity of fat is perhaps the most important from the standpoint of total solids, in that it is most variable of all the solid ingredients of milk. With an increase in the total solids, fat increases and ash

decreases, whereas casein and albumin remain practically the same, as is shown in the following table, compiled from 2,400 American analyses at the Vermont Experiment Station:

TABLE II.[5]

AMOUNT OF INGREDIENTS IN 100 POUNDS OF TOTAL SOLIDS.

Quality of Milk as to Total Solids	Fat	Casein and Albumin	Milk sugar and Ash
Per Cent	*Lbs.*	*Lbs.*	*Lbs.*
11	27.9	29.5	45.5
12	29.1	25.6	45.2
13	30.7	25.4	43.9
14	33.4	25.5	41.2
15	35.8	26.6	37.4
16	37.5	26.8	35.6

When buying by the quart for general use, those who are looking for "rich milk" are entirely right in judging their milk by the percentage of fat shown by analysis or by the cream gauge. The cream gauge is, however, an inaccurate method of judging fat, for a milk showing a relatively small percentage of cream by the gauge may make more butter, *i.e.* produce more butter fat than one showing a relatively large percentage of cream. Professor Caldwell reports that Baumhauer in Amsterdam examined 20 different samples of milk. Nos. 1 and 2 were found by chemical analysis to have respectively 2.7 and 3.5 per cent. of fat, while Nos. 5, 10, 15, 18, and 20 were found by accurate chemical method to contain 3.3, 3.0, 3.9, 2.3, and 2.7 per cent. of fat, and yet the thickness of the layer of cream formed by all of them was the same.[6] There is not, then, any close connection between the cream percentage and the butter yield or true fat percentage.

Being a liquid, we are prone to look upon milk as a mere drink rather than a food, whereas in it are contained all the elements necessary to the maintenance of the human body, and evidence is to be had in abundance showing that milk is in no sense a luxury, but is an economical article of diet. Meats and milk are both rich in protein and are, in a sense, interchangeable as regards food value. Consequently the amount of solids in the milk becomes of great importance.

We are told that a quart of milk, twelve ounces of beef, and six ounces of bread all represent about the same amount of nutriment, and yet only that can be considered as true nutriment to the body which is digested and assimilated, and under different circumstances these three substances may have entirely different food values.

Where mere food content, without respect to the personal equation of the animal to be fed with it, is the main point of consideration, that milk is a good milk which has a high percentage of solids, and since variation in percentage of solids depends largely upon that of fat, that milk is, as a rule, the best milk which gives the largest percentage of fat. However, food content and food value are not always equivalent, due to variation in the powers of digestion and assimilation in the individual to be fed. But, where commercial value, either for butter or for other by-products, is the only point at issue, a milk must have a high percentage of solids in order to be "good." Where weak digestion is to be dealt with this is not true.

(2) *Good Skim Milk.*—Certain breeds of cows always head the list in percentage of butter fat, but when the quantity of fat per cow is taken or when the value of the whole milk is calculated, giving each ingredient its respective value, the order of standing shifts itself entirely.

To those who have seen the country milkmaid skim off the cream and set aside crock after crock of skim milk to be, as it seemed, "thrown out" to the pigs and chickens, it is hard to give any adequate conception of the value of skim milk until by analysis and by the still more important test of results in feeding it, we are brought to realize that butter fat is not the only element worthy of consideration in our estimate of milk and cows. Cream is valuable chiefly for its heat-giving properties, and the skim milk contains the valuable protein. The following table shows what we have left in skim milk according as the cream has been removed by skimming or by centrifugalization:

TABLE III.[12]

	Gravity	Separator
Fat	.9	.1
Casein and albumin	3.2	3.6
Sugar	4.7	5.
Ash	.7	.8
Water	90.5	90.5
	100.0	100.0

Of what value is this? To answer this question I can do no better than to draw extensively from the article cited on "Milk as a Food" and from the article by C. L. Beach which gives the results of experiments conducted for the purpose of showing the relative food value of solids from milk poor and rich in fat content when fed to young growing animals. Even after milk is skimmed it still contains nearly 10 per cent. of its own weight of solids or nutritive ingredient, and the value of skim milk as a food is not generally appreciated. In an exclusive milk diet one has to drink a large quantity to get the needed nourishment, but when taken with bread or used in cooking it forms a very nutritious addition to the food. A pound of lean beef (round steak, for example) contains about 0.18 pound of protein and has a fuel value of 870 calories. Two and a half quarts, or 5 pounds, of skim milk will furnish nearly the same amount of protein and have almost the same fuel value as the pound of round steak. Two quarts of skim milk have a greater nutritive value than a quart of oysters, and the nutriment in the form of oysters would cost from 30 to 50 cents, while the two quarts of skim milk would have a market value of from 4 to 6 cents and a value on the farm of from 2 to 4 cents. An oyster stew made of one part oysters and two parts skim milk would owe its nutriment more to the milk than to the oysters. A lunch or meal of bread and skim milk is very nutritious, as the following computation shows:

TABLE IV.[8]

COMPOSITION AND COST OF A LUNCH OR MEAL OF BREAD AND SKIM MILK.

Food Materials	Amount	Estimated Cost	Protein	Fuel Value
		Cents	*Pound*	*Calories*
Bread	10 oz.	3	0.06	755
Skim milk	1 pt.	1	[illegible]	170
Total	.....	4	[illegible]	[illegible]

The following lunch, such as might be obtained

in a restaurant or lunch room, will serve for the purpose of comparison:

TABLE V.[8]

ESTIMATED COST AND NUTRIENTS OF A RESTAURANT LUNCH.

Food Materials	Amount	Estimated Cost	Protein	Fuel Value
	Ounces	*Cents*	*Pound*	*Calories*
Soup	8	.....	0.01	75
Beef	2	.....	.02	275
Potatoes	2	.....	.....	100
Turnips	1	.....	.....	15
Bread	4	.....	.02	300
Butter	½	.....	.....	100
Coffee:				
Milk	1	.....	.....	20
Sugar	½	.....	.....	55
Total	.....	15 to 20	.05	940

FIG. 1.—Pig fed on skim milk.

It will thus be seen that the 15-cent lunch containing nine different food materials did not have any greater nutritive value than the 4-cent lunch of bread and milk.

The ingredient of our food which costs the most, which has the greatest physiological value, and which is most apt to be lacking in ordinary dietaries

FIG. 2.—Pig fed on milk poor in fat

is protein. Skim milk has nearly all the protein of the whole milk. By the removal of the fat in the cream it loses half its fuel value, but practically none of the protein. What is left has all the value of the whole milk for building and repair of tissue, for the making of blood, muscle and bone, and half the value of the whole milk for supplying heat and muscular power. When the facts are fully understood, skim milk will doubtless be more wisely utilized.

The fact comes home to us even more forcibly in the presence of such experimental demonstration of the value of skim milk as is found in the excellent work of C. L. Beach. When separate lots of pigs were fed skim milk, milk poor in fat and milk rich in fat respectively, for the first forty days the pair receiving skim milk gained 62 pounds; the pair receiving milk poor in fat, 54.8 pounds, and the pair receiving milk rich in fat, 42.2 pounds. For the next ten days the gain for each pair was 22 pounds, 20 1-2 pounds, and 3 1-2 pounds, respectively. From 50 to 60 days the results were 20 pounds gain, 21 pounds gain, and 6 pounds loss, respectively. After 40 days' feeding the pair receiving the milk rich in fat were affected with loss of appetite and diarrhea, and finally did not consume enough to sustain life. The pair receiving skim milk maintained good appetite until the close of the trial. The pigs fed milk rich in fat also consumed more solids for a pound of gain, showing that the excess was not assimilated but only acted to cause a diarrhea and eventually loss of weight rather than gain.

The results of slaughter showed also that the pigs fed skim milk gave better meat and better bone than

FIG. 3.—Pig fed on milk rich in fat.

those fed milk rich in fat. Fig. 4 shows the result in graphic form.

The same principle was demonstrated by him on other animals, as is shown in the following tables:

TABLE VI.[5]

SOLIDS FOR ONE POUND OF GAIN WITH CALVES.

	Milk Poor in Fat 3.27%		Milk Rich in Fat 5.1% 4.6%	
	Calf No. 1	Calf No. 2	Calf No. 3	Calf No. 4
	Lbs.	*Lbs.*	*Lbs.*	*Lbs.*
Solids for one pound of gain	1.16	.91	1.33	1.03
Solids for one pound gain, average of each pair, lbs.	1.03		1.08	

TABLE VII.[5]

MILK SOLIDS REQUIRED FOR ONE POUND OF GAIN, AVERAGE OF SIXTEEN ANIMALS.

	Milk Poor in Fat	Milk Rich in Fat
	Lbs.	*Lbs.*
Average of 2 pair calves, 45 days	1.03	1.18
Average of first trial, 2 pair pigs, 40 days	1.36	1.77
Average of second trial, 2 pair pigs, 30 days	1.40	1.56
Average of 2 pair lambs, 60 days	1.08	1.37
Average of 8 pair animals	1.22	1.47

Table VII. shows in each case that the pair receiving the milk poor in fat required less food for a

pound of gain than the pair receiving the milk rich in fat; and the average for the former was 20 per cent. less.

The failure of a pound of milk solids in rich milk to make equal or better gain than a pound of solids in poor milk was not due, apparently, to lack of nitrogenous material, but rather to the excess of fat or to the character of the fat. Larger fat globules were found in the richer milk, and this fact in connection with the digestive disturbances would seem to indicate the reason for the larger gain from a pound of solids with the poorer milk.

Another element of value for the skim milk is the fact that from it are made the different forms of cheese.

The average composition of buttermilk, which is practically sour skim milk, is quite similar to that of skim milk, though it contains slightly less protein and sugar and a very little more fat. The fuel value is about the same, about 165 calories per pint. An ordinary glass of buttermilk contains as much nourishment as half a pint of oysters or 2 ounces of bread, or a good-sized potato.

(3) *Large Quantity.*—A large quantity of whole milk affords a large quantity of skim milk, and, if

Fig. 4.—Showing the difference in the meat of pigs fed on skim milk and on milk rich in fat

a milk can be found from which an equal quantity of fat can be extracted daily and still have a large residue of skim milk for feeding young growing stock or other consumers, the advantage is only too evident, especially when experiment has shown conclusively that the young growing animal thrives better on skim milk or milk poor in fat than on milk rich in fat. Other things being equal, the milk of a cow giving a large quantity is more desirable than that of a cow giving a small quantity, for reasons other than mere quantity as such. In a cow producing a large quantity of milk one is sure to find a rugged constitution, good powers of digestion and secretion, depth of respiration, and good physiological traits in general. Such a cow is also more liable to be free from tendencies to disease.

(4) *Slow Creaming.*—This quality would necessarily indicate a good emulsion. Rapid rising of the cream shows that the fat globule is for some reason or other unable to maintain its original relation to the menstruum in which it is suspended. Usually the immediate cause of the rapid rising of cream is the large size of the fat globules. The specific gravity of fat being less than the remaining constituents, the larger the fat globules, the faster it rises. Viscosity and other elements of the milk may be instrumental in modifying the process, but, whatever the cause, rapid rising of the cream shows poor stability of the emulsion. Hence, for numerous reasons slow creaming can be looked upon as a decided advantage in any milk. After the cream has risen by the gravity method there still is retained in the skim milk a goodly proportion of fat which is made up of the finer globules whose specific gravity did not differ sufficiently from that of the milk to carry them to the surface in the allotted time. A certain proportion of fat is also necessary to a good cheese, which is the chief by-product of skim milk.

Certain forms of cod liver oil give great trouble in digestion on account of their irritability to the gastrointestinal tract, due to the difficulty of obtaining the requisite emulsion of the fat necessary to assimilation. That artificial preparation of it which retains its purity and most completely breaks up the fat globules, and thus forms the most stable emulsion, will most nearly fulfil the requirement for which it is prescribed. The intimate analogy with the case in hand would admit the statement in regard to milk that the more complete and stable the emulsion, other things being equal, the more digestible the milk.

Another point under this head is worthy of attention. In the retail delivery of milk that milk will be most just for all consumers which divides the solid constituents equally among all. This is impossible in a milk in which fat, *i.e.* cream, rises rapidly, for in such case the larger proportion of fat goes to those served early from the can.

(5) *Easy Remiscibility.*—After cream has once separated from the milk it so adheres as to make it practically impossible to again reduce the milk to its former condition by shaking. That the difficulty of remixing the fat with the remaining constituents varies markedly with different milks is easy of demonstration. With some specimens the fat globules are broken up and butter produced without obtaining the thorough emulsion which existed before separation. This element is very important in such cases in artificial feeding of infants when one mixes enough to last for twenty-four hours and allows it to stand between the different feeding periods. As a general rule a milk with globules of large size mixes poorly after separation of the cream, and the milk which is originally the most perfect and stable emulsion returns most readily to its original condition on shaking.

(6) *Slow Churning.*—The smaller the fat globules, the longer the time required for churning. This was demonstrated experimentally by Dr. Sturtevant. Butter churned from a milk of large fat globules gives a butter of coarser grain than one of small globules. In the churning process the first molecules to form in a milk with small globules are very small. A slow-churning milk is also as a rule one in which the cream rises slowly and hence has this advantage also, as shown above. Furthermore, in a milk which churns easily one is frequently able to find small particles of butter churned during the ride necessitated by delivery of the same in a retail business. This is specially undesirable with infants and invalids.

(7) *Small Fat Globules.*—This quality insures slow creaming, good emulsion, easy remiscibility, ease in digestion and assimilation, and better skim milk with its by-products. There is an element of extreme importance in the examination of milk which chemical analysis will not reveal, viz., the size of the fat globules. Milk is an emulsion of fat in a menstruum composed of substances in solution and suspension in water. Various milks differ ma-

terially in the size of their fat globules. In the experiment on pigs cited above, in which milk rich in fat, milk poor in fat, and skim milk were fed to separate sets of pigs with the advantage so overwhelmingly in favor of the skim milk, the size of the fat globules was measured in the milk rich in fat and poor in fat respectively, and it was found that the average diameter of the fat globules in the poor milk as compared with those in the rich was as 2 to 3.5 and their volume as 1 to 5. This was probably the basis of the trouble with digestion in the pigs, as I shall show later.

It is a well-known fact that certain Jersey cows give milk so rich in fat that they cannot suckle their own young. It is at least to be suspected that the trouble is not so much in the "richness" of the milk as in the large size of the fat globules. The smaller the globules of fat, the more permanent the emulsion, and also the less irritation to the gastrointestinal tract. Also, the finer the emulsion, the easier the process of digestion and assimilation, as will be shown under another head.

Wing gives the size of fat globules in cow's milk as varying between 1-1500 and 1-25000 of an inch in diameter, the extremes of which I consider too small and too large respectively, when all milks are considered. Foster gives the size of the human fat globules to be from 1-5,000 to 1-2,500 of an inch. By accepting these measurements, made by different investigators under different circumstances, some writers have held that fat globules in human milk are smaller than those of cows' milk. This, however, is not the case. Nowhere have I been able to find any comparative estimates of the relative size of the globules in human and various dairy cows' milk in which all samples investigated were submitted to the same methods. Being informed by the Department of Agriculture at Washington that no such investigation had been made in which accurate comparison of the various breeds of milk had been stated, I measured the fat globules of human milk and of the milk of four of the chief breeds of dairy cows, viz., Jersey, Guernsey, Ayrshire, and Holstein. The samples used were taken from a mixture of the milk of the pure-bred cows of the respective herds, and all submitted to the following conditions: In order to facilitate ease of measurement by getting the globules separated more widely in the field than could be done with whole milk, one part milk and two parts water were mixed. To this mixture was added a small amount of liquid rennet, so as to coagulate the casein and thus help hold the fat globules stationary under the microscope. Before coagulation took place one drop of the mixture was mounted on a slide and under a cover glass. The process of coagulation of the casein helps to remove the slight quivering and motion of the globules which otherwise hamper one in the measurement. In subsequent investigations a thick solution of gum acacia was used and was even preferable to the rennin method. A 1-12 inch objective was used, the correction to microns having been calculated for the micrometer scale. One thousand globules were then measured, taking them as they came. This was done by measuring all that fell between two of the large divisions of the scale on the micrometer disc, and then as the field was shifted by means of the mechanical stage all falling within the space thus covered were measured and the average for the 1,000 taken and the results subsequently reduced to microns, *i.e.* 1-25,000 of an inch, generally designated by μ. The human milk was a mixture of specimens from five women whose babies were respectively 7, 4, 3, 2, and 1 months old.

In order to determine how large a variation there was from the average, the average variation was also calculated for the respective samples of milk.

TABLE III.

SIZE OF FAT GLOBULES IN DIFFERENT KINDS OF MILK.

	Human	Jersey	Guernsey	Ayrshire	Holstein
Average diameter in microns or μ	2.9	2.8	2.6	2.1	2.0
Average variation in microns μ	1.2	.9	.85	.76	.69

There being such variation in diameter, the variation in volume is all the more striking when the relative size is represented graphically, as in Fig. 5.

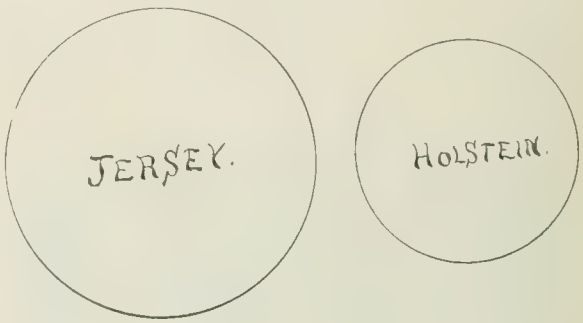

FIG. 5.

Thus the average Jersey globule has 2.7 times the volume of the Holstein globule. The human is still greater than the Jersey.

Sturtevant in his excellent work showed conclusively that the larger the globule, the shorter the time required for churning, as is shown in the following table:

TABLE IX [1]

AVERAGE SIZE OF GLOBULE*	Time Churned. Minutes	Butter First Showed
5680″	3	.....
5940″	8	5 min.
6768″	25	15 min.
8252″	50	36 min.
8320″	60	.....

The milk, then, with a large globule is at a decided disadvantage where transportation of the milk is a necessity.

(8) *Uniformity of Size of Fat Globules.* — This quality insures more stability to the emulsion, and hence such milk is more easily assimilated, as explained above and verified below by experiment. Table VIII. gives the variation in size of globules for the various breeds.

(9) *Slow Coagulation.*—It has long been known that the curd of cow's milk gives trouble when fed to infants, and in modification of the same sufficient water is added to reduce the quantity of the casein approximately to that in human milk. This still leaves a curd which is at times troublesome, and lime

*Sturtevant's measurements were all in fractions of an inch, and all globules smaller than one unit of his micrometer were not counted or measured and were designated as granules. He used lower magnifying power. The so-called granules having been omitted in his average, direct comparison of results is impossible except relatively.

The sign ″ signifies fractions of an inch, *e.g.* these figures are to be read 1-5680th, 1-5940th of an inch, etc.

water is added to help dissolve it. Aside from these facts there are other differences between the coagulum of human and cows' milk.

To test coagulation I heated to 100° F. a water bath containing a 15-c.c. test tube, in which was placed 10 c.c. of milk, in which one drop of liquid rennet was well mixed. The water bath was then allowed to stand and gradually cool at the rate of about 1 degree in five minutes, with the test tube remaining in the bath until coagulation of the milk took place. The time was noted when the milk began to solidify, which occurs rather abruptly. This could be detected by tilting the test tube occasionally. Jersey milk coagulated in 29 minutes, Guernsey in 31 minutes, Holstein in 34 minutes, and human milk failed entirely to solidify after standing for days, though an increased thickness was manifest after standing a considerable length of time. Repeated tests gave practically the same relative results except in one instance. On this day when I called for milk at the Jersey and Guernsey dairy I was told that the cows had bloated on pasture that day so badly that one Jersey cow died. This day the milk coagulated in 17 and 23 minutes for Jersey and Guernsey, respectively. On mixing cow's milk with water in the ratio of 1 of milk to 2 of water, so as to reduce the casein to approximately that of human milk, then cow's milk also failed to solidify even after standing 48 hours. It, however, took on a thickened aspect also. There was a marked cohesion of the particles as compared with the human specimen.

There was also this marked difference in the coagulum of human and diluted cow's milk. As human milk coagulated, after standing some time the casein floated, the whey clearing gradually from the bottom. The casein of cow's milk sank and the clear whey appeared at the top instead of at the bottom as in human milk. In the test tube containing human milk a slight sediment also formed in the bottom of the tube which on examination under the microscope proved to be fat globules. With the data at my disposal any attempt at explanation of this by me at present would be ill-advised.

One more distinction might be noted. After shaking the coagulum of human milk it became very fine, whereas the coagulum of cow's milk could be seen clinging to the tube.

It would seem evident that for purposes of digestion a slow, fine coagulation would be preferable to the coarser, more rapid one. This subject presents a valuable field for further investigation, which unavoidable circumstances render impossible at present.

(10) *Easy Absorption and Assimilation.*—To test whether a milk with small fat globules would be absorbed from the intestine more easily than one with large ones, I isolated a cat and fed him on milk and water exclusively for four days, feeding him once in 24 hours. This was done to clear the intestine of food previously eaten. On the fourth day he was given a meal of separator cream (Jersey being used because of its large fat globules) and killed an hour and twenty minutes afterward by illuminating gas asphyxiation. Chyle was then taken from the ducts of the mesentery and also the upper half of the intestine was emptied. The fat globules of each specimen were measured to get the size of those in the intestine and mesentery, respectively, to see if in absorption there was preference for globules of small size. The difference under the microscope was very marked. The specimen from the mesentery contained globules that were very small and so exceedingly uniform in size that only 350 were measured and an average taken. The average and average variation for both specimens were calculated. The results were as follows:

TABLE X.

SIZE OF FAT GLOBULES IN INTESTINE AND MESENTERY.

	In Intestine	In Mesentery
Average diameter in microns.	2.2	1.6
Average variation in microns	[illegible]	.31

The results show very plainly that small globules have the preference in absorption and the average variation in size of those absorbed is so small that there can be no doubt that large globules are absorbed with relative difficulty. It will be noted also that the average globule in the intestine is also smaller than that of the Jersey globules as fed, showing the emulsification or at least selection of the fat in process of digestion. During asphyxiation the cat vomited a large amount of white fluid, apparently but little changed, judging from gross appearance.

(11) *Good Keeping Qualities.*—This bespeaks purity and freedom from destructive agencies. It is a well-known fact that milk which is drawn under surgical cleanliness and asepsis and immediately sealed hermetically and brought to a temperature of 60°F. will keep for weeks. Hence keeping qualities are dependent in part at least upon cleanliness, which, however, is not the only element.

(12) *Cleanliness and Purity.*—This goes without saying. The normal product of the udder is all that should be found in an ideal milk.

(13) *Phlegmatic Temperament in the Cow.*—Inasmuch as fright, worry, shock, or other derangements of the nervous system show themselves in the quality and quantity of the milk, that cow which is least affected by the disturbances necessarily incumbent on surrounding conditions will, other things being equal, give the best milk. Instances are not infrequent in which calves have died shortly after taking the milk of the cow which had been previously subjected to severe shock or long-continued nervous strain. That worry or fright will affect the quantity of milk is a matter of common observation.

(14) *Healthy, Rugged Cow.*—Good milk production presupposes good digestion, healthy secretion, vigorous respiration, and active circulation. In short, the chief end of the cow is milk production, and when the latter is at its best the cow producing it must be of such a nature as to respond to the unusual demands made upon her by such process of secretion. Some cows are under continual strain and never go dry, usually performing the function of reproduction simultaneously with the performance of their most useful function, viz., the production of milk.

(15) *Freedom from Disease in the Cow.*—Disease such as tuberculosis can be transmitted through the milk, and hence that cow or breed of cows which is least susceptible to the inroads of disease is to be preferred to one whose methods of breeding have rendered them more or less subject to infection with the diseases to which cattle are subject.

COMPARISON OF DAIRY BREEDS.

The great mass of people know but little of breeds beyond the fact that "Jerseys give rich milk." Being desirous of comparing only the chief dairy breeds, the following will be dealt with, viz., Jersey, Guernsey, Ayrshire, and Holstein-Friesian.

Fat is the most variable quantity in milk. The percentage of solids not fat is practically a stable quantity in various milks, and hence the commercial value of a milk is estimated by its percentage of fat. In percentage of fat, Jersey cows lead the list, but not so in the daily quantity of fat per cow, if we are to accept the following report of the United States Department of Agriculture, by Lane, in 1905:

TABLE XI[6]

SUMMARY OF AMERICAN ANALYSIS OF SAMPLES OF MILK FROM PURE-BRED COWS

BREED	No. of Cows	Fat in Milk Per Cent.	No. of Cows	Average Daily Milk Yield in Lbs.	Average Daily Fat Yield in Lbs.
Jersey.....	164	5.13	153	24.5	1.26
Guernsey...	67	4.87	53	28.9	1.41
Ayrshire...	33	3.85	18	27.7	1.07
Holstein-Friesian..	502	3.30	493	48.9	1.61

It will be seen from this table that in percentage of fat the respective breeds would stand in the following order: Jersey, Guernsey, Ayrshire, Holstein; but when quantity of fat is considered, the order shifts as follows: Holstein, Guernsey, Jersey, Ayrshire. The cause for this difference is to be found in the quantity of milk yield of the various breeds. While the Jersey yielded only 24.5 pounds of milk a day, the Holstein yielded within one-tenth of a pound of twice that quantity, viz., 48.9 pounds. Remembering the exceedingly high value of skim milk as a food, and remembering also that the percentage of solids not fat is practically the same in various milks, in the light of her milk production the Holstein would seem to be the preferable cow to own. One not only gets more fat per cow, but nearly double the amount of skim milk, which contains the valuable protein.

On the other hand, those buying milk by the quart, sold at a uniform price for all breeds, will receive more commercial value by purchasing Jersey milk, for in so doing they get a milk with a higher percentage of solids. Where good digestion, adults eating a mixed diet, and highest commercial value per quart are the only elements to be dealt with in choice of a milk, the Jersey is undoubtedly the preferable milk. Where infants, weak digestion, and large quantity of milk are at stake, the Holstein leads the list and the Jersey becomes the least desirable for numerous reasons indicated by the qualities enumerated in the discussion of qualities desirable in a milk.

Jerseys have been bred with butter mainly in view. Alvord gives the annual milk product per cow as 5,157 pounds, yielding 293 pounds of butter, which includes the average of 140 cows for 6 years. The characteristic of the milk of this breed is a high percentage of total solids, especially fat; 4 to 5 per cent. of fat is a usual rate, and in many instances it is still higher. Jersey butter records based upon percentage of fat are correspondingly large. The butter fat is in globules of uneven size and large on the average—larger than in other breeds—and hence cream is easily separated and comparatively hard to remix. The quantity of milk is small in accord with the general rule that a high percentage of fat is usually accompanied by a small milk yield. Jersey milk coagulates quickly and, having large globules, would be relatively hard to absorb from the intestine.

Jerseys are the smallest of the noted breeds in average size, the cows ranging from 700 to 1,000 pounds and the bulls from 1,200 to 1,800 pounds. With this light weight is to be found frequently a tendency to delicacy of constitution. In no sense are they a beef breed. They do not fatten readily, and hence have a poor showing at the block. In good animals all extra food is converted into milk. It is interesting to note that originally the Jerseys, because of their resemblance to deer, were bred to adorn the lawns and parks of the English aristocracy.

Typical Jerseys generally have a high-strung, nervous temperament, and in order to do their best must receive good care and dare not be abused as to food or treatment, without injury. Bulls are hard to handle. In one local dairy (now changed to Ayrshire) two valuable imported bulls had to be shot because they were so vicious that handling was fraught with too much danger.

The breeding qualities seem impaired when compared with other breeds. Under extreme care and nursing it is difficult to raise as high as 90 per cent. of the calves. One local breeder gave up the breed and changed to Ayrshire because, as he expressed it, "In spite of all I could do, my Jersey herd just faded away from me." He lost 50 per cent. of his calves with Jerseys, and since the change to Ayrshire, on the same farm and under the same conditions, he has lost but one calf out of 107. When asked as to the cause of death in the Jerseys, no apparent cause was known. He said, "They were just weak. They lay around as limp as a rag and died." The manager of the local Jersey herd (one of the finest in the country) is by extreme care able to raise 90 per cent., which is far above the average.

Jerseys are alert and suspicious of the stranger, and frequently will not give down their milk in the presence of a stranger, to say nothing of a strange milker. A glance into their stall is generally met by a quick look as if of surprise and inquiry.

Guernseys.—The cows of this breed produce liberal quantities of milk, and it is of uncommon richness in butter fat and in natural color. They are to be recommended for butter cows as well as for market milk where quality secures a relatively high price, and they are noted for rich production combined with especial economy in feeding. The annual milk yield of good herds of Jerseys and Guernseys of the same number is just about the same. They are markedly a butter cow; the fat globule is next to the Jersey in size, and hence a rich yellow cream rises quickly and in goodly quantity. The fat globule being large, it suffers the same handicap as Jersey milk in the relative ease of absorption. Like the Jersey, the cream mixes rather slowly after separation.

Guernseys are a size larger than Jerseys, stronger boned, and a little coarser in appearance. They possess great power of assimilating food and converting

it into milk, yet are delicate feeders rather than gross, and will not generally bear much forcing. The Guernseys possess a nervous temperament, and yet the cows are extremely quiet and gentle when properly handled, and less trouble is reported in the management of aged bulls than with Jerseys of like age. They also fatten better than the Jerseys.

Ayrshires.—The average annual product of milk per cow is 5,412 pounds. The milk of the Ayrshire is not exceptionally rich, but somewhat above the average. Herd records show 3 1-2 to 4 per cent. of butter fat in the mixed milk throughout the year. The milk of this breed is very uniform in its physical character, the fat globules being small, even in size, and free to separate from the milk. Cream rises slowly and has comparatively little color. The Ayrshire, therefore, is not a first-class butter cow, but its milk is admirably suited for town and city supply, being safely above legal standards, uniform, and capable of long journeys and rough handling without injury. In its slow churning and easy absorption it has the advantage of the two breeds mentioned above.

The breed is among the youngest of well-established type, having been built up within the nineteenth century by a liberal use of blood from the cattle of England, Holland, and the Channel Islands. The Ayrshire of the present day bears strong resemblance to the Jersey in certain features and to the wild white cattle of Chillingham Park, from which they are probably descended. It is practically certain that they are descendants of the original wild cattle of Great Britain.

The Ayrshire excels in obtaining subsistence and doing well on a wide range of scanty pasture or in thriving and giving a dairy profit upon the coarsest forage. They are of medium size, probably averaging 1,000 pounds, and bulls from 1,400 to 1,800 pounds. Being of a highly nervous temperament, the cow has superabundance of nerves and is willing to employ them upon instant demand for self-defense or self-support. The bulls, if properly handled, are not fractious, but the cows are rather inclined to be quarrelsome. They are always active and energetic, stop only for a purpose, move off with a brisk walk, and often trot without special provocation—points of both interest and value.

Although these cattle can lay no claim to being specially adapted to beef production, the calves are thrifty and full-fleshed, and steers and dry cows fatten readily on suitable feeding. All in all, the Ayrshire is a good cow.

Holstein-Friesians.—These large black and white cows yield milk in proportion to their size. The breed is famous as enormous milk producers. Records are abundant of cows giving an average above their own live weight in milk monthly for ten or twelve consecutive months; 7,500 to 8,000 pounds per year is depended upon as a herd average. Holstein milk is characterized by fat globules of small and uniform size, separating slowly by the gravity method, churning slowly, and carrying very little color. Set side by side with milk of no richer quality but of larger fat globules, in a given time less depth of cream will rise.

The peculiar structure of this milk renders it specially valuable for cheese making, as the fat globules are more readily retained in the curd. It also adds to the value for marketing, as the cream rises very slowly and remixes easily. The color of the butter is a lemon yellow rather than an orange, and its keeping qualities are unexcelled, as is shown by Dr. Sturtevant, an advocate of the Ayrshire breed.

"One sample of Dutch (Holstein) butter, one of Guernsey butter, and seven of Jersey butters were placed in a cupboard adjoining a steam heater. A few days later another part of Ayrshire butter was added. The Guernsey butter was very high colored, melting point 99°, had an oily rather than a waxy look, but was very attractive. It moulded in spots in about a month. In seven weeks the Jersey butters were all rancid and one had lost its color in spots, the white spots reminding of tallow—no butter flavor. The Ayrshire butters were not rancid, but had lost flavor and were poor. The last specimen placed in the same cupboard, but on an upper shelf, was forgotten. When examined three and one-half months later it still retained its butter flavor, but was not first class. The Dutch butter was well preserved, being neither rancid nor flavorless."

Assuming that all specimens were subjected to the same conditions in preparation, this testimony, coming from an advocate of the Ayrshire breed, becomes exceedingly important.

Because of the low percentage of fat, Holsteins have been looked upon by some as poor butter yielders, an error arising out of a confusion of percentage of fat and quantity of fat per day. One author states that "allowing to the Jersey breed the standard yield of 200 pounds of butter per annum, the Friesian (*i.e.* Holstein) and Swiss cows would produce 239 pounds." In further confirmation of the incorrectness of the claim, let me give a table from Bulletin No. 102 of the Wisconsin Experiment Station on "Studies in Milk Production."

TABLE XII.

	Holstein	Guernsey	Jersey	Short Horn
Average annual yield of milk	9987.3	6530.7	5700.2	7121.4
" " " " fat	351 6	319 4	301 1	281.7
" " value of product	$94 63	$82.31	$77 10	$74.26
" " cost of food	45 46	37 37	35.22	38.15
" " net profit	48.17	44.94	41.80	36 09

This table, if accurate, leaves but little room for argument from the commercial standpoint.

Holstein milk coagulates the most slowly of any, and on account of its small globules and their evenness in size it has a decided advantage in ease of absorption.

This breed can be traced back for two thousand years and was always famous for dairy purposes. In breeding, the object of the breeders has always been to produce as much milk and beef as possible from the same animal, and the results bespeak their success. The large frame, strong bone, abundance of flesh, silken coat, extreme docility, and enormous milk yield make a combination truly to be desired. In size the Holsteins are the largest of all dairy breeds. It is difficult to prevent the males from becoming too fleshy for breeding animals, and the females when not in milk take on flesh rapidly. The cows average about 1,200 pounds. The bulls at maturity are very large and heavy, often above 2,500 pounds in weight.

This element of size is a very important one, for "it may be stated as a general law that the food of support decreases proportionately with the increase of size in animals; . . . size, all other things being equal, is favorable to the economical yielding of milk. It actually takes less food to produce a hundred pounds of milk with a cow of equal merit weighing 1,000 pounds than with one weighing 800 pounds." In a comparison of breeds the Wisconsin

station decided in favor of the larger, hardier, more vigorous cows.

In temperament these animals are quiet and docile, bulls as well as cows, the bulls exceptionally so. Instead of being held at bay with a long stick hooked in the nose-ring, they can usually be led out for exhibition at the end of a loose rope. Among the cows, instead of a fretful suspicion of strangers one frequently has to guard his clothes against their too friendly curiosity, while calves of other breeds are likely to put the longest distance possible between themselves and a newcomer.

No breed excels them in great constitutional vigor, and the calves are large at birth, almost always strong and thrifty, growing fast, and fattening easily. This vigor of constitution is shown not only in the large, healthy physique and great resistance, but also in the regular and persistent breeding characteristics. A grade Holstein almost invariably shows the predominance of the Holstein, no difference how or with what other breed it is crossed. Not only color, but other characteristics are transferred.

Their robustness makes them specially resistant to disease, whereas the more delicate breeds, such as the Jersey, have sad tales to record from the ravages of such diseases as tuberculosis. They are easy of acclimation, having penetrated successfully to within 3 1-2° of the arctic circle.

All in all, if one were choosing a human wet nurse he would look for just the characteristics in her that we find presented in a Holstein cow, viz., vigorous constitution, quiet, easy-going temperament, uninfluenced by external disturbances, good glandular development, abundance of good milk, freedom from disease or tendency to disease, a good healthy child of her own, and good family history.

In reviewing the qualities of a good milk as enumerated in the first part of this article, it will be seen that the Holstein cow fulfils most completely all the requirements except the one demanding a high percentage of solids, and even here when quantity of fat instead of percentage is considered she more than holds her own. Also in the face of the fact that a milk poor in fat is better for the young growing animal than milk rich in fat, the advantage of high percentage of fat in a small quantity of milk can readily be sacrificed to a low percentage of fat in a large quantity of milk when human food for infants and invalids is under consideration.

Whether we are to grant any such thing as a vitality peculiar to a milk or not is a disputed question. However, Professor Carlyle of the Wisconsin Experiment Station is quoted as saying that the Physicians and Surgeons' Association of Chicago recommends the milk of a certain Holstein dairyman receiving 12 cents a quart because for some reason not understood it has more vitalizing power than any other milk they can get. If such be the case it is highly probable that closer chemical and microscopical analysis would reveal the physical qualities which render the milk more digestible and assimilable, which qualities are covered by this vague expression, "vitalizing power."

Inasmuch as the milk of a Holstein cow most nearly fills all the requirements for a good milk, it will not seem amiss to go a little further into detail regarding this trade mark of Holland, if I may so call her.

For 2,000 years the Holstein cattle have been bred in the confines of Holland as milk, butter, and beef producers, and the results obtained have shown the remarkable success of these quiet, unassuming Dutch. The average American would balk at the prospects of paying a land rent of $15 to $20 an acre, and yet "here are people occupying lands which seldom are sold for less than five hundred dollars per acre, more frequently for a thousand and upwards, producing butter and cheese and placing it upon the European market in successful competition with that produced on lands less than a tenth of their value." To those of us who associate foul odors and disgusting slime with the idea of a cow stable it seems repulsive to think of human beings living under the same roof with their cows. Yet this is what the Dutch did for centuries and still are doing with extreme cleanliness and purity of life. "It is no exaggeration that the cattle every day during the winter are washed off with warm soapsuds, dried, rubbed, coddled, and talked to as if they were children, that the air in the stable is as pure as the atmosphere outside, and that no pains are spared to keep them healthy and comfortable. Under such kind treatment they become such plump, glossy, and gentle animals that they repay their owners by an enormous quantity of milk." Is it any wonder that 2,000 years of such life should produce the quiet, docile, friendly animal that we know the Holstein to be? "Their milch cows are never driven by dogs. They are rarely beaten or subjected to other rough treatment. Not that these Holland dairymen are marvelously good tempered, but they recognize the fact that such treatment is poor economy. They have learned that all nervous excitement of whatever nature lessens milk production. Hence, not only in management but in breeding they seek to perpetuate quietness of disposition. The uneasy, fighting temperament that a class of American dairymen is trying to exalt into a bovine virtue they regard as a great vice in a milch cow. Their cows are rarely seen uneasily ranging their fields. They seldom have conflicts with one another or display any disposition for mastery. They display social tendencies. They love to be petted. Children caress them without fear, and strange persons entering a herd are regarded with friendly curiosity rather than with terror or belligerency."

"It is found in more countries than any other breed, occupying more territory, and is probably producing more milk, cheese, and butter than all others combined."

Says an advocate of the Holstein: "It is hard to be compelled to bear the taunts of those who are continually throwing the 'skim milk' characteristics of the Holsteins into their owners' faces, but as long as these despised cows produce over 10 per cent. more butter and over 100 per cent. more milk than the Jerseys or Guernseys, their breeders will probably continue in their foolish ways and stick to the Holsteins."

REMARKS ON CESAREAN SECTION, WITH REPORT OF A CASE.

By PAUL F. MARTIN, M.D.,

INDIANAPOLIS.

ALTERNATE VISITING SURGEON TO THE INDIANAPOLIS CITY HOSPITAL.

In no other field has modern surgery shown more progress than in the evolution of cesarean section, for which no greater testimony can be offered, and no better evidence shown, than by the glorious results accomplished to-day. It is no longer regarded as an operation of hazard with a most frightful mortality, but, on the contrary, possesses advantages even superior to other obstetrical procedures which are in common practice. Some salient points bearing on this phase might not be deemed amiss.

Craniotomy, with a maternal mortality ranging from 6.6 to 11 per cent., subjects the mother to greater danger, and sacrifices the life of her babe. The child, though unborn, has inherent rights to life, which demand respectful consideration. While symphyseotomy judiciously regards the rights of the child, and possibly spares his life, it assures an added risk from infection to the mother, and materially reduces her chance of recovery. The maternal death rate from this operation, according to the latest statistics, reaches as high as 14.4 per cent. With due respect for life, and with full benefit to both mother and child, cesarean section crowns the efforts of the modern surgeon, reducing the maternal mortality to 5.4 per cent., and the infant mortality to almost *nil* (Sloane Maternity Hospital, New York City).

It may be mentioned that expectancy has no place in the category of alternatives in treatment, and should be discarded as such. It has served its day, concealing with the cloak of wisdom the lamentable ignorance of the accoucheur. Facing certain death of mother or child, or both, he waited, utterly helpless to avert the bitter end; for did he not also fear the threatening warning against surgical interference in the pregnant woman? The advent of surgical asepsis and improved hospital equipment, together with the efforts of the progressive and skillful abdominal operator, stand alone responsible for the complete revolution of this supposedly established obstetrical principle.

Williams says spontaneous delivery of an ordinary full-term child cannot take place in pelves of 7 cm., that the absolute indication of cesarean section should be fixed at that point, and that the relative indications should be extended in cases with a conjugate vera of 8.5 cm. in flat pelves, and 9 cm. in generally contracted pelves. He furthermore states that if the head fails to engage in an hour after completion of the first stage, under favorable circumstances cesarean section is indicated, and that by it nearly all children will be saved, and quite as many mothers as after difficult forceps operation, or version, or craniotomy.

During the past six years five cases have come under my personal attention or treatment, four of which occurred during my service on the surgical house staff of the German and Sloane Maternity Hospitals in New York City. In the latter institution occurred the only death, which was not due to the operation, but a result of the disease from which the patient was suffering. She was brought to the hospital moribund from pulmonary tuberculosis, besides having a large fibroid, firmly adherent, and completely obstructing the parturient canal. Succumbing in the first stage of anesthesia, an instantaneous incision and a marvelously quick delivery by Dr. Edwin Cragin, gave birth to a well-nourished babe, soon lustily crying. Two other cases at the same institution, and one at the German Hospital, operated upon for contracted pelves, made uneventful recoveries. The last of the number, which furnished the incentive for this paper, occurred at the Indianapolis City Hospital during my incumbency as superintendent of that institution.

A report was made and read before the Indianapolis Medical Society, November 7, 1905, of which I beg to submit a brief summary:

On the morning of July 24, 1905, about four o'clock, the writer was called to the delivery room of the obstetric ward at the City Hospital. The patient was in the second stage of labor. The following history was given:

H. G., 17 years old, white; housewife; primipara. Mother died of pulmonary tuberculosis; father died of pneumonia; no brothers or sisters.

Personal History: Of the diseases of childhood, patient had measles and scarlet fever; no history of rickets; after puberty frequent attacks of bronchitis and of indigestion; history of slight leucorrhea; doubtful history of gonorrhea; that of syphilis, rheumatism, malaria, pelvic diseases, and injury, negative. Menstrual history, negative. No pregnancy until the present one; the first day of the last menstruation was September 15 (doubtful); three days in duration and large in amount; no pain; quickening felt at sixth month; no history of vomiting, but severe headaches and swelling of lower limbs during gestation. The late period of quickening felt by the mother dispels the thought of possible prolonged gestation, which the doubtful data of the patient's last menstruation might lead one to suspect.

The patient had complained of a sensation of giddiness since eleven o'clock on the previous morning, of uncertain vision, and of intervals of temporary blindness and repeated and frequent emesis. She had had ten eclamptic convulsions of varying intensity since noon. The convulsive attacks were accompanied by complete unconsciousness, during the intervals the patient remained only semiconscious. The pulse was tense and hard, varying in rapidity from 92 to 112; respiration from 18 to 36; temperature from 101.2° to 100.8°. The laboratory report of the uranalysis upon admission showed sp. gr. of 1012, acid in reaction, amber in color, no albumin, no casts. Labor pains had started early in the afternoon, and at 7:30 P.M., during the convulsion, the membranes ruptured spontaneously. With complete dilatation forceps application was undertaken, and at the time of my arrival a second unsuccessful attempt was in progress, the patient being under the influence of chloroform. Abdominal examination elicited clear fetal heart sounds situated posteriorly in upper left quadrant, frequency 150; uterine souffle absent. Vaginal examination revealed some edema of the vulva, a narrow parturi-

ent canal, a correspondingly small pelvis, edematous cervix and a large caput succedaneum, markedly interfering with the localization of the sutures and fontanelles. The vertex was found firmly imbedded in the left oblique diameter, occiput posterior, obstinately resisting any attempt at dislodgment. The pelvimeter recorded the following measurements: Distance between spines, 20 cm.; between crests, 25 cm.; left oblique, 20 cm.; right oblique, 19 cm.; external conjugate, 17 cm., and true conjugate, 7.50 cm. The combined conditions of eclampsia with a justominor flat pelvis, a living child, and the mother in fair condition, offered but one indication—cesarean section, for which preparations were at once instituted.

The distended bladder had reached a line midway between the pubic crest and the umbilicus, catheterization by the nurse having proved unsuccessful, on account of both the bruised and edematous parts obliterating the normal relationships, and the obstructing head of the child, which was firmly wedged in the pelvis. Further attempts to empty this viscus were thought inadvisable.

Operation was performed with the assistance of Drs. John Wallace, Larue Carter, Charles Sudranski, and Fred Dickson. A five-inch median incision through the skin and down to the peritoneum was made, carefully avoiding the full bladder, and extending upwards to two inches above the umbilicus. The peritoneum was opened and the posterior attachment of the placenta determined. Two quick longitudinal incisions four inches in length opened through the uterine wall and into the uterus, followed by immediate podalic delivery of the child with membranes, and aftercoming placenta, with simultaneous grasping of the cervix by the first assistant, which checked the bleeding admirably. The hemorrhage on incising the uterus was surprisingly small, due to the instantaneous forceful contractions of the uterine wall, distinctly blanching the muscle fibers as they receded from the cutting edge of the knife. In like manner the placenta was freed from its posterior attachment, but the fetal head was extricated with some difficulty from the bony pelvis. The child, almost black from deep asphyxia, was resuscitated by means of Schultz's method of artificial respiration, blowing into the mouth, slapping, and alternately immersing in hot and cold water until it was crying lustily.

The uterine cavity was closed without irrigation or drainage. The uterine sutures employed were a double row of muscular interrupted chromic gut, and a continuous chromicized gut suture for the serous coat, inverting the edges, and covering the whole line of suture with the omentum. The peritoneal wound of the abdominal incision was closed with a continuous catgut suture, the muscle with interrupted chromic gut, fascia with continuous chromicized gut, and the skin with interrupted silk sutures. On the eleventh day the abdominal sutures were removed; primary union had occurred. On the twenty-third day the breasts were dry; fundus not felt; lochia absent; patient out of bed.

Examination of child at birth: Sex, male; temperature, 99°; weight, 6 14-16 pounds; length, 50 cm.; caput succedaneum marked.

Diameters: Suboccipito-bregmatic, 8 cm.; suboccipito-frontal, 11 cm.; occipito-frontal, 11.5 cm.; occipito-mental, 13.5 cm.; biparietal, 10 cm.; bisacromial, 12 cm. Circumferences: Occipito-frontal, 35.5 cm.; suboccipito-frontal, 33.5 cm.; bisacromial, 35 cm.

Placenta and cord normal. No anomalies found on child except a mark, resembling an entirely healed scar, on the anterior aspect of the left leg, extending about 8 cm. above the ankle. The mother presents a similar scar above her left ankle, which she claims is a birth mark. The baby was put to the breast of another woman having an abundance of good milk, and thrived. On the twenty-eighth day after the operation the mother and child were discharged from the hospital, both in good health.

This case is reported by reason of its rather unusual nature, in that it presents a case of eclampsia in a patient with a markedly contracted pelvis. It was obvious that there was only one course to pursue, the complicating toxemia only emphasizing the urgent need of immediate action. This eclamptic attack is noteworthy, because of the absence of the usual accompanying renal elements, and exemplifies that type of toxemia resulting from fecal intoxication. There was no evidence of organic lesion other than increased tension of the pulse, with accentuated second aortic sound, a low excretion of urea, and a slight rise of temperature.

The respective pelvic and fetal measurements demonstrate that a natural termination of labor was impossible, and, furthermore, that the extrication of the living child could have been accomplished only with the aid of surgical interference. The conservative operation, viz., without castration, was done by reason of the age of the patient, assuming that with development into mature womanhood the pelvis would naturally broaden, and possibly permit of a succeeding pregnancy terminating in a natural labor.

Naturally, the first impulse was to evacuate the obstructing full bladder. However, the danger from abdominal paracentesis, preliminary to the operation, I considered much greater than the risk of hemorrhage from opening the uterine sinuses before gaining their control, by means of uterine delivery into the wound and compression of the uterine arteries. The course pursued resulted in a surprisingly small flow of blood, and in practically no escape of uterine contents into the abdominal cavity.

It is not my province to advocate the broadening of the field for cesarean section, yet it is obvious that the brilliant successes and the superior possibilities offered by this method of delivery must necessarily narrow the indications for other obstetrical procedures, which, if not primarily destructive in character, tend to increase the death-rate of the principals.

224 North Meridian Street.

THE JOINT AFFECTIONS OF HEMOPHILIA

By JOHN G. SHELDON, M.D.,

KANSAS CITY, MO.

Acute affections of the bones and joints, especially in children, are so important from the standpoint of treatment, and are so serious when they have not been properly dealt with, or when proper treatment has been unduly delayed, that an occasional rehearsal of the essential points of these diseases is excusable. To those of us who at some time have neglected to recognize a beginning acute osteomyelitis in a child, and to those who have unknowingly opened hemophilic joints, repetitions of the important diagnostic features of joint diseases are not without interest. For these reasons I offer, without apology, that which is generally well known concerning a rare, but exceedingly important, joint affection.

The joint manifestations of hemophilia have been studied for years, but on account of the condition being rare, it took time to learn the truth. The

earlier writers—Elsasser, Lange (1851), Grandidier, and others—thought that these patients suffered from a combination of diseases. They contended that these peculiar cases were examples of gout and rheumatism in hemophiliacs. In 1868 Volkmann showed that slight trauma was frequently followed by hemorrhage into a joint in bleeders. Later Legg, Charcot, Lossen, Poncet, König, Redfern, Reinert, Paul Wagner, and others, showed that these joint affections were in no way associated with rheumatism or gout, but were the result of bleeding into the joint. A primary hemorrhage resulted in little permanent change in the joint, while repeated hemorrhages were followed by marked and permanent changes in both the soft and bony structures. Some of the specimens described by Legg closely resembled arthritis deformans.

The symptoms of these cases have been divided into three stages by König: (1) in which intraarticular hemorrhage is the only change; (2) after repeated hemorrhages have resulted in marked articular and periarticular changes, and have limited joint motion, and (3) when the process has resulted in ankylosis. Although the joint may pass through all of these stages, the early symptoms are the most important, and should be carefully studied. As a rule, the primary joint involvement comes at the age of four or five years (Legg). It may, however, occur shortly after birth, or be postponed until the patient is well grown. In Case 2 in this report, and in a case reported by Brigstocke, the symptoms developed a few days after birth, while Wagner (*Deutsche Zeitschrift für Chirurgie*, December 18, 1884) reports a case in which the first joint involvement occurred during the twenty-first year.

In the primary attack, the joint, with or without the history of a slight injury, suddenly becomes painful, swollen, hyperemic, and tender. The pain is extreme, while the tenderness is not marked. Evidences of fluid in the joint cavity are present. A rise of temperature is the rule. A chill is not to be expected. The symptoms subside in about a week, only to be repeated by future involvements. Every attack leaves its evidences of having done permanent injury to the joint. The swelling and limitation of motion remain; or deformity and even ankylosis may be present.

The importance of diagnosing these joint affections cannot be overestimated. The history of the case is most important. In the primary attack, a leucocyte count may aid in excluding infections, but aspiration of the joint, followed by examination of the withdrawn fluid, should be resorted to in doubtful cases. In diagnosing old cases the history of previous attacks is most important. An infection sufficiently severe to disorganize a joint would not get well in a week.

In treating acute cases, the joint should be aspirated by using a small needle. This diminishes the pain and at the same time doubtless assists in preventing the occurrence of permanent joint changes. Nothing can be done for the old cases. König opened two of these joints by mistake. An Omaha surgeon has opened another. Another was cut into in Göttingen. All of these patients died from bleeding from the operation wounds.

Case I.—M. W., a girl, six years of age, received a slight blow on her left knee by being struck by a small gate swinging in the wind. The injury did not cause much pain at the time it occurred, but four hours later the joint began to swell and was extremely painful. The pain was so severe that the family physician was obliged to give morphine to control the patient. I saw the child fourteen hours after the knee became involved and found the joint markedly swollen, the skin over the knee hyperemic, and evidences of fluid in the joint cavity. There was a marked disproportion between the pain and the tenderness. The pain was extreme, but the tenderness was not marked, while passive motion did not increase the suffering as much as would have been expected if the condition had been an acute inflammatory one. The temperature was 103° F., the pulse was 110. No chill had occurred. Leucocytes, 7,800. The child had had no previous illness of moment, but had bled from the nose repeatedly and sometimes seriously. An uncle gave a plain history of being a bleeder. On account of the elevation of temperature, it was feared that an infection was present, so the joint cavity was aspirated. About three and one-half drams of blood was removed. Cultures from this blood were found to be negative. The removal of the blood from the joint gave considerable relief. In forty-eight hours the temperature was normal and the pain gone. The knee appeared to be normal after five days. The patient was kept in bed for two weeks, after which time she became active and did not complain of the knee. Six months later she again injured the knee slightly by falling. The symptoms of the previous attack were repeated, except that convalescence was more prolonged and the swelling did not entirely disappear. Three months after this second attack the joint is occasionally painful, seems larger than its fellow, and it is clearly noticeable that the girl favors the left knee in walking or running.

Case II.—During my service as an interne in Cook County Hospital, Chicago, a male infant, otherwise apparently normal, developed, on the fourth day after birth, a condition that to all appearances was an acute arthritis of the right ankle joint. It was thought at first that in some unaccountable manner the joint had been injured. But the appearance of the joint did not suggest an injury as the cause. The character and extent of the redness and swelling, together with a temperature of 102.8° F., looked like an infective process. On the sixth day after birth the child began to bleed from the bowels. The next day blood was vomited and a few small hemorrhages appeared under the skin. There was no bleeding at the umbilicus. Death occurred on the ninth day after birth—five days after the appearance of the joint involvement. Two hundred c.c. of a 2 per cent. solution of gelatin was injected under the skin, with no noticeable effect. A post-mortem examination showed blood in the right ankle joint, but revealed no definite cause of death. This was thought to be a case of hemophilia, although the mother, on account of knowing little of her relatives, could give no history of hemophilia in the family. Bacteriologically this case was negative. Examination of the contents of the involved ankle joint showed no microorganisms. As soon as the child was dead blood was aspirated from the right auricle. This failed to produce any growth on the ordinary culture media.

Case III.—I am indebted to Dr. J. N. Goodson for the report of this case. A boy twelve years of age, who gave a history of repeated nose-bleed and excessive loss of blood following slight wounds, rapidly developed a condition that closely resembled an acute arthritis of the left knee. The pain was extreme and the swelling and redness marked. The temperature was elevated from one to three degrees and the pulse rate was correspondingly quickened. A "Spanish fly blister" was applied. In a week the acute symptoms had subsided. Previous to the illness the boy had suffered from a similar, but less severe, attack. At the age of eleven years the knee

had suffered from its first involvement. No history of traumatism preceded either attack. After the illness which has been described the left knee remained swollen and tender and its motion was somewhat limited. About six months after the second involvement of the knee occurred the boy developed, quite suddenly, a hemorrhage from the bowels. The hemorrhages continued and resulted in death after three days.

THE MORTALITY FROM LOBAR PNEUMONIA IN HIGH ALTITUDES.

A SUMMARY OF THE STATISTICS AT THREE MILITARY HOSPITALS IN ARIZONA AND NEW MEXICO.

By ISAAC W. BREWER, M.D.,
CONTRACT SURGEON U. S. ARMY.

Although the text-books on the practice of medicine are silent about the relation of altitude to the mortality from lobar pneumonia, many of the members of the profession who practise in such localities, and a large portion of the general public, are of the opinion that the disease is very much more fatal than at places near sea level.

The question has been studied by a number of physicians, and their opinions are by no means unanimous.

In 1882 Dr. E. Sanders,[1] in a paper on the geographical and climatological relations of the disease, based upon the returns of the eighth and ninth census, and other data, comes to the conclusion that "With increase in elevation above the level of the sea, there is a steady diminution in the death rate from pneumonia."

Hoagland[2] found that the mortality for hospitals in Colorado, in cities that varied from 4,700 to 10,000 feet above the sea, was less by 5 per cent. than the rates for hospitals in Philadelphia and other cities near sea level.

Van Zant believes that at Denver the disease runs a more rapid course.

Swan thinks that in the Rocky Mountain region the disease is more curable than at lower levels.

Connell[2] comes to the conclusion that altitude has very little to do with the mortality from pneumonia.

Major C. F. Kieffer[3] of the Medical Department of the Army has recently studied the disease at Fort D. A. Russell, Wyoming, elevation 6,195 feet, for the 36 years ending with 1903, and finds that the rate at that station was 1 per cent. less than that for the army as a whole during the same period.

Dr. A. R. Goodman[4] from the City of Mexico, elevation 7,348 feet, reported 101 cases, with a mortality of 37 per cent.

Galbraith from Cananea, Mexico, elevation something over 5,000 feet, recently reported 50 cases without a death.

The first case that came under my observation in this region was in the person of a rather dissipated rancher, who was admitted to the hospital in a critical condition with a right-sided pneumonia. Naturally, after hearing that the disease was very fatal at this altitude, I expected him to die, but, on the contrary, he made an uneventful recovery, as did all of the cases treated in the hospital that winter. These results caused me to look up the cases that had been treated in the post hospital. During the following year I was temporarily at Forts Grant and Wingate, and collected the data from those posts.

Fort Huachuca is situated in the southeastern portion of Arizona, at an elevation of 5,042 feet above the sea. Its annual mean temperature is 60°, the highest temperature recorded was 104° in July, and the lowest 7° in December and January. The winter nights are cool and at times quite cold, but the days are generally warm. The annual precipitation averages about 16 inches.

Fort Grant is about sixty miles north of Fort Huachuca, and has practically the same climate.

Fort Wingate is situated in the western portion of New Mexico, at an elevation of 6,822 feet. The mean annual temperature is 61° and the average precipitation about 14 inches.

All of these posts are west of the continental divide, and, excepting for the high winds that prevail in the spring and early summer, the climate is delightful.

The records of these posts cover the period from 1884 to 1904, and in all there were 61 cases of lobar pneumonia treated, with a mortality of 18 per cent., while for the army at large for the same period the mortality was 17.4 per cent.

The mortality varied from year to year. From 1884 to 1888 it was 37 per cent.; from 1889 to 1903 it was 10.5 per cent.; from 1894 to 1898 it was 40 per cent., and from 1899 to 1903 it was 5.5 per cent.

The distribution of the lesions was as follows: Right lung, 44 per cent., mortality, 7.4 per cent.; left lung, 30 per cent., mortality, 22.2 per cent.; both lungs, 13 per cent., mortality, 37.5 per cent.; not specified, 13 per cent., mortality, 37.5 per cent.

Thirty-three per cent. of the cases occurred in the spring, with a mortality of 19 per cent. Seven per cent. of the cases occurred in the summer, with a mortality of 25 per cent. In the winter 44 per cent. of the cases occurred, the mortality being 18 per cent., while in the fall the percentage of cases was 16 and the mortality 20 per cent.

At Fort Wingate, the most elevated of the stations, there were but eight cases, and the mortality was 12.5 per cent. At Fort Huachuca, the next lower station, there were 28 cases, with a mortality of 18 per cent., and at Fort Grant, the lowest station, there were 25 cases, with a mortality of 20 per cent.

Of the 61 cases reported herein, 54 were amongst the whites, with a mortality of 25.4 per cent; 15 cases were amongst the colored soldiers, with a mortality of 26.6 per cent., and the remaining 2 cases were in Apache Indian Scouts, neither of whom died.

The statistics here presented are too few for generalization, but, compared with the Army at large, they seem to show that elevation has little to do with the mortality from lobar pneumonia. Comparing the stations themselves, we find that the mortality varies inversely with the altitude.

Cost of Medical Education in England.—The student, on entering one of the London medical schools, pays £20 entrance fee, in addition to an annual charge of £30; that is to say, £170 ($850) for the five-year course. The extras for special courses amount to about £15, and books, instruments, etc., say, £30 more. When examination fees, say 40 guineas, are added, and the official register fee, £5, we get, roughly, £280 ($1,400). Clothing, board, and other necessary expenses bring the total for the five years to about £900 ($4,500).

CHOLELITHIASIS.

IN almost no other abdominal disorder is a thoroughgoing study of the underlying pathological conditions more essential to a proper therapeutic attitude than is the case in dealing with what may comprehensively be termed gallstone disease. In view of their greater facilities for actually inspecting many different phases of the morbid processes involved, it is not unreasonable to look to the surgeons rather than to the internists for advances in this field, and accordingly one finds that of late there appears to be something of a change in the manner of regarding the therapeutic indications in cases of this sort. The tendency now is to relegate the gallstone itself to a rather subordinate position, and to regard cholelithiasis as an infectious disease in which an inflammatory process of the gall-bladder and biliary passages is the most important feature. Kehr has but crystallized the opinion of many others in saying that "the stone in the gall-bladder is *per se* a fairly innocent formation. I am unable to recognize a cholecystitis without infection." In other words, the significance of gallstone disease lies not in the gallstone, but in the coexistent infectious cholecystitis, and in the severity of this infection and its spread through the larger and smaller bile ducts. Thus, Körte obtained positive results in seventy-six operative cases that were examined bacteriologically, and Riedel has estimated that although in Germany there are about two millions of gallstone carriers, only about one in twenty suffers any discomfort from the condition.

Aldor of Karlsbad, writing in the *Berliner klinische Wochenschrift* of September 17, 1906, not only upholds the importance of the infectious element, but expresses his belief that the origin of the disease is closely associated with catarrhal conditions in the intestine. An examination of the stools in one hundred cases of cholelithiasis examined while free from jaundice in every instance revealed evidences of intestinal disorders. Chronic constipation is held to be an especially frequent precursor of cholelithiasis, but acute catarrhal disorders are comparatively rare in this connection. Aldor also asserts that more conservatism in operating is necessary, and that prominent surgeons like Kehr as they gain in experience restrict more and more the indications for surgical intervention. These are said to comprise acute and chronic empyema of the gall-bladder, frequently recurring attacks of cholecystitis that are not amenable to internal treatment, and blocking of the common duct accompanied by chills and jaundice. The standpoint of those who would place early operation on the gall-bladder in the same category with early operation on the inflamed appendix is criticised severely, on the ground that the conditions are fundamentally different, and greater perseverance and thoroughness in medical treatment, particularly the Karlsbad cure in one form or another, are urged.

This reasoning is in sharp contravention to the opinions of many operators, particularly in this country, who see in the gall-bladder only a vestigial organ embodying grave possibilities for harm to its bearer and to be dispensed with without detriment. The question is one that will probably for some time remain a matter of individual opinion, at least until the advocates of early operation have amassed sufficient statistical material to enable comparisons to be made on very large numbers of cases.

THE KINDERGARTEN.

THERE is a certain period which may be described as extending from the fifth to the seventh year, when the young hopefuls have formulated demands as regards their occupation which can no longer be satisfied by the nursery or its methods. Yet their age is such that they cannot be subjected to the restraints of the primary school grades and the acquirement of the elementary knowledge of the three "R's." The advent of that institution which manifests its German origin in the appellation of "kindergarten" was regarded by educators and mothers as a means whereby the young child could be properly guided by the use of eyes, ears, and fingers to be prepared for later mental efforts, and so the little toddlers were gathered into a room for several hours daily and taught to weave pretty little mats with colored strips of paper, to make pretty little mud pies, to sit in a circle and sing pretty little songs with a pretty little teacher in the center of the group. All of these things appealed to the mother, who, in many instances, may have been animated by the desire to get rid for a few hours daily of the youngsters, who were at an age when getting into mischief and asking embarrassing questions was apparently their main desire. And so Froebel's idea grew in popularity, and even the public school authorities were in time compelled to listen to the clamor, establish kindergartens, and provide specially trained teachers.

To careful observers among educators the objections to restraining young children in this manner soon became evident, but their only reward was to be called "old-fashioned." This epithet will also probably be applied to N. L. North, who voices his objection to the method in a communication in the *Brooklyn Medical Journal* for June, 1906. He calls attention to the severe strain to which the eyes, only partially developed at this age, are subjected in making the various paper mats and other useless articles of which the kindergartner is so fond. It has been actually proved, moreover, that the average child who is free from care and kindergarten obligation until the seventh year will do better work than his classmate who has been occupied for two or more years in the manner described. What growing

children need is plenty of fresh air, sunshine, and exercise, and their physical rather than their mental faculties should be cultivated. The restraints imposed by confinement in a schoolroom are irksome enough after the seventh year, when it has become necessary to acquire the knowledge which our civilization has deemed it fit that we possess. Before that period the cultivation may better be extended to the body, so that the vegetative processes may be developed and perfected to such an extent that disease may be resisted and the mind prepared for the demands to be made upon it in later years.

THE FETICH OF THE OVARY.

Under the above suggestive title Van de Warker has published a timely and interesting paper in the *American Journal of Obstetrics* for September, 1906. There are still a great many gaps in our knowledge of the physiology of the ovaries, and these two little organs which play such an important part in the life history of woman have been forced to assume the burden of many responsibilities which may be said to be largely based on this lack of information. If they apparently failed to fulfill the demanded requirements, it was a simple matter to remove them; but the unfortunate outcome in many cases finally prompted a reaction to an opposite extreme, and the ovary, instead of being ablated, was punctured, burned, resected, replaced, and otherwise maltreated.

Pelvic pain in women has been almost universally referred to inflammation of the ovaries rather than to a limited peritoneal process in the same region which is known to be very frequent. Ovaritis is rare and when uncomplicated is not a painful condition. Inflammatory processes may extend all around the ovary without involving its stroma, and the painful symptoms which are ascribed to this organ are due largely to adjacent adhesions and old abscess cavities, yet, as Van de Warker points out, "inflammation of the ovary" is still the explanation offered for these symptoms. The presence of small multiple cysts has likewise afforded an excuse in many instances for an oophorectomy when none was needed. Displacement of the ovaries has been considered a factor in the production of menstrual and intermenstrual pain, although it has been shown repeatedly that an organ might be displaced to a considerable degree by adhesions or new growths, without its migration having caused any discomfort to the patient.

This continuous clamor about the ovaries has, according to the writer, its sociological reflex, for the wholesale castration which has, unfortunately, been practised by many well-meaning but misguided operators, has resulted in direct increase of the percentage of sterility. Women have had their attention drawn to this alleged ovarian disease and are thus led to give undue importance to the organs in the presence of any pelvic disturbance. Then, again, the operation from which so much was expected by the victim has only too often been without results other than unfavorable ones. It is not improbable that in many instances the patient needs more ovarian substance rather than none at all, and the removal of what remains only makes the condition worse; from all of which it appears that the author of this paper is justified in pleading for a more careful consideration of the existing condition in any case of supposed ovarian disease so that operators may be led to refrain from the indiscriminate ablation and mutilation of these organs.

Glandular Fever in Children.

Among the complaints of obscure origin prevalent in children is an acute swelling of the lymphatic glands, which, with its accompanying symptoms, was described by Pfeiffer almost twenty years ago and is now again attracting attention on account of its frequent occurrence. Abroad it also constitutes a topic of interest, and among the most important of recent articles is one by Cheinnisse in *La Semaine Médicale,* No. 26, 1906, which, however, adds very little to Pfeiffer's description of the disease, nor are we any better informed as to its etiology. The affection usually begins with a sudden rise of temperature to 103° or 104° F., pains in the joints, vomiting, and general malaise. A swelling of the lymphatic glands is soon noted, those along the posterior border of the sternomastoid muscle usually being first involved. The fever may subside in a few days, together with the glandular swelling. But there are cases in which the fever lasts for eight to ten days, other glands become affected, and the mucous membrane of the pharynx shows a marked hyperemia. Difficulty in swallowing and cough are believed to point to an involvement of the retro-esophageal and retrotracheal groups, hypogastric pain to that of the mesenteric glands. The disease often assumes an epidemic character, but the outcome is usually favorable, and only in exceptional instances do we meet with suppuration in the affected glands. There is another, a subacute form, in which the glandular swelling is accompanied by diarrhea, slight albuminuria, and other evidences of an involvement of the abdominal glands. It has become a quite generally accepted opinion that the condition is not a local process limited to the lymphatic glands, but an infectious disease which must be distinguished from acute idiopathic inflammation of the cervical lymph nodes. Strepto-, staphylo-, and pneumococci, as well as the influenza bacillus, have all been described in connection with this condition, but this fact does not constitute a factor against the disease as a clinical entity. It has been claimed that this form of adenitis is merely secondary to an infection of the pharyngeal mucous membrane. Such an argument is apparently contradicted, however, by the complications, such as an acute nephritis, and by the epidemic character of the disease. The fact that, despite the high fever and the marked swelling of the glands, there is rarely suppuration present also seems to speak for a virulent general infection rather than a localized process. The condition has been particularly prevalent in New York during the past year, and it would appear to be the part of wisdom, in view of the apparently infectious character of the complaint, to isolate these children as a matter of precaution.

A Test of Purity of Hypodermic Solutions.

The value of subcutaneous administration of medicaments is quite generally recognized, but the method has its limitations and objections, chief among which is the possibility of carrying infection into the system through the medium of the injected material. Suppuration in the form of an abscess not due to the needle puncture is not uncommon, and tetanus has even been reported in a number of cases in which gelatin has been used. Unexpected and undesirable sequelæ of similar nature have likewise followed preventive inoculations and the therapeutic employment of diphtheritic and other sera. It has thus far been a difficult matter to test satisfactorily the sterility of a serum or other material

intended for subcutaneous injection. Cloudiness is an uncertain evidence because it may be due to an ordinary precipitation of the globulins, and yet this is one of the commonly accepted signs. An Italian, Prof. Gosis, and his assistant, Giorgi, have, however, recently found that the salts of tellurium and selenium are thrown down in the form of a dense precipitate in the presence of bacterial growth (*Medico-Technologisches Journal,* No. 17, 1906). The addition of these salts to sera or other fluids intended for subcutaneous injection is said in no way to interfere with the action of the latter, as shown by numerous experiments with lymphs, sera, solutions of strychnine, morphine, citrate of iron, arsenite of sodium, and gelatin. It is essential that the fluid used should have an alkaline reaction. Details of the process are not at hand, because the discoverer, as is quite customary abroad, has patented the method.

Tuberculosis and Bronchial Asthma.

Among the very many etiological factors which have been adduced to account for the production of asthmatic attacks, it is quite commonly believed that affections of the respiratory passages occupy an important position. The influence of lesions in the upper portions of the respiratory tract has been much disputed, but the frequent coincidence of asthma and pulmonary tuberculosis in the same individual or among members of the same family makes it very probable that there exists an intimate connection between these two conditions. An investigation of this subject has recently been conducted by Soca (*Archives générales de Médecine,* No. 26, 1906), who examined seven hundred cases of bronchial asthma and found an apparently tuberculous basis in about five hundred. In some instances the tuberculous process and the asthma appeared at the same time, but in the greater number the asthma came on first, to be followed by the symptoms of the other after varying periods. Another group of cases includes those in which the patient affected with tuberculosis became asthmatic at some later period of the disease. In about two hundred cases there does not seem to have been any evident connection between the two diseases, although the writer acknowledges that in most of these the period of observation was not sufficiently extensive. There seems to be evidence enough, however, to warrant the assumption that in many instances there is present an intimate connection between the two affections, and in every case of asthma it would therefore be the part of prudence to make a careful examination for the signs of tuberculous disease of the lungs.

Twenty-four-hour Pneumonia.

A characteristic form of pneumonia to which the above title has been applied is marked by a rapid elevation of temperature with complete defervescence within a period of from twenty-four to forty-eight hours. The general symptoms and the local signs are like those of ordinary pneumonia, but they last only for the brief period stated. Nordmann, in the *Gazette des Hôpitaux,* No. 69, 1906, presents some recent statistics which show that among 1,057 cases of pneumonia this form was found ten times. A case is described which is typical of the condition. The patient was seized with a chill, vomited, and complained of intense pain in the side. The fever which followed subsided suddenly within two days, accompanied by profuse sweating and polyuria. The physical signs were those of an ordinary pneumonia, and even the sputum was typical. The convalescence was uneventful. This form of pneumonia is found to attack young, healthy individuals and the prognosis is favorable. The course of the disease and its occurrence in groups seems to point to a type of infection which, for some reason or other, has become weakened. If such a type of pneumonic infection really exists, it is quite probable that in most instances it will be overlooked, as the brief period involved would lead the physician to believe that some condition other than a pneumonia had been present.

News of the Week.

International Association of Medical Museums.—Under the auspices of the United States Army Medical Museum at Washington, through its curator, First Lieutenant James Carroll, Assistant Surgeon, U. S. A., steps are being taken for the formation of an organization having the above title. At a preliminary meeting held in Washington at the time of the session of the Association of American Physicians a committee on organization was appointed, consisting of Dr. Carroll as chairman, Dr. W. G. McCallum of the Johns Hopkins Medical School, and Dr. Maud E. Abbott of McGill University, Montreal. At the session of the Section on Bacteriology and Pathology of the British Medical Association in Toronto, on August 24, Dr. Carroll made an official announcement of the aims and objects of the proposed association. At this meeting it was proposed that there should be two grades of membership in order to include museum workers as well as those who represented institutions. It is designed that the association be essentially one of institutions rather than of individuals, each institution being entitled to a single vote through its representative, the museum representatives being the active members. The auxiliary membership is to comprise persons who are actively engaged in museum work, but these will have no vote. It is also proposed that there be an honorary membership, to be conferred upon members of the profession eminent in the field of pathology but who are not engaged in museum work. For the present it is designed that meetings shall be held triennially in Washington, at the time of the meeting of the Congress of American Physicians. The meetings are to be devoted to addresses and discussions of matters of general interest, and the publication of an *index pathologicus* is also projected to facilitate the interchange of specimens.

Hospital Conference.—A meeting of this organization of hospital superintendents will be held at the Academy of Medicine on Tuesday afternoon, October 30, 1906. The regular order of business will be supplemented by a discussion of the recently promulgated system of uniform hospital accounting. The conference will be invited to consider, also, a plan for collecting and preparing, in suitable form, the facts upon which its collective reasoning and its joint action for the "promotion of economy and efficiency" in hospital management should be based. The President is Rev. George F. Clover of St. Luke's Hospital, and the Secretary is Dr. S. S. Goldwater of Mount Sinai Hospital.

Meeting of the Illinois State Board of Charities.—At this meeting, held at Springfield, October 18 and 19, Dr. Daniel R. Brower of Chicago

intimated that politics is allowed to interfere with the efficiency of the management of the State charitable institutions, and declared that for years the interference of politicians with the officers of the State institutions had nullified efforts at good management. Governor Deneen retorted with much feeling, giving a flat denial to such intimations or charges so far as his own administration was concerned. Dr. William A. Evans of Chicago spoke on "Care of Consumptives in the State Institutions." On this point Dr. Evans said that all occupants of jails, prisons, and insane asylums should be examined by physical examination and with tuberculin for consumption. Persons with consumption should be segregated and treated by the open-air method as adapted for such cases. In view of the general acceptance of the danger of mixing the tuberculous and non-tuberculous, he asked whether, if a State did not so segregate its criminals, would it not be liable for damages to those contracting consumption? Dr. George W. Webster of Chicago presented a paper urging that the State should authorize the State Board of Health to manufacture and furnish free of cost to citizens of Illinois all the antitoxin needed for the treatment or prevention of diphtheria. He argued that this was a public health measure, designed primarily for the protection of the well. He quoted from reports of Chicago, New York, and other cities to show that antitoxin would not only prevent diphtheria, but would cure the disease, and declared that it would prove a paying investment for the people of the State by prolonging life, and also in dollars and cents, citing the experience of Massachusetts, where the annual cost of supplying free antitoxin is $10,000, while the amount used would otherwise cost the people $135,000. The main recommendations of the Board, which will necessitate several legislative enactments for their fulfillment, are as follows: The establishment of a State psychopathic institute for the education of institution physicians and the scientific study of diseases of the brain and nervous system; the establishment of compulsory training schools for nurses and attendants; the establishment of bath treatments for hopeful cases of insanity; industrial reeducation for chronic types; physical improvements to place the buildings and equipment in better condition; the establishment of a State village for epileptics; the establishment of a State sanatorium for consumptives; a second hospital for the feeble-minded.

Vermont State Tuberculosis Commission.—The members of the Vermont State Tuberculosis Commission, believing that their work is now well organized and that it can best be continued under the auspices of the State Board of Health, in their biennial report, soon to be submitted to the Legislature, will recommend the abolishment of the commission. They will also recommend that the work of the commission be transferred to the State Board of Health, and that a bill be passed by the Legislature for an annual appropriation of $2,000, the sum which the commission has expended annually in its work, to be used by the Health Board for the same purpose.

A Magazine for the Sightless.—The first magazine for the blind to be published in this country, and the second of its kind in the world, is being planned for and will probably soon be issued. The funds for the enterprise are being supplied by Mrs. William Ziegler, and it is intended to supply the periodical free of charge to all blind persons. Owing to the high cost of books printed for the blind, very many of those who have learned to read in institutions are unable to put this knowledge to use after returning to their homes. The new magazine will contain stories of the news of the day, fiction, special articles designed to interest blind people particularly, an industrial department wherein blind people may find information as to the lines of work in which they are engaged, and a correspondence department. Both the Braille and the New York point systems will be used, so that those who have learned either one will be able to read the magazine. It is desired that the addresses of as many blind persons as possible be sent to Mr. Walter G. Holmes of 1931 Broadway, New York, who is organizing the plant.

New York Infirmary for Women and Children.—This institution, which has just celebrated its fifty-third anniversary, during the last year treated 1,043 patients in the hospital, 10,809 in the dispensary, and 8,968 at their homes by visits paid by the infirmary staff. Efforts are being made to raise the sum of $30,000, which is needed to complete the total of $124,000 required for the new buildings at 2 and 3 Livingston place.

Sanatorium for Hebrew Children.—Mr. Jacob H. Schiff has presented the sum of $4,200 to this institution for the purchase of a tract of land at Rockaway Park adjacent to the present sanatorium property.

A New Disease of Cattle.—A "strange and unknown" disease with rapidly fatal results is announced to have appeared among the cattle of Kern county, California, especially among those feeding near swamps recently under water north of Buena Vista lake. A bacteriological investigation has not yet been made.

Compulsory Vaccination at Los Angeles.—Although the State law requiring all school children to be vaccinated as a qualification for admission has been neglected in many parts of the State, it has been rigidly enforced in this city during the past month. From 500 to 1,100 children have been vaccinated daily, free of charge. Unfortunately, more than 1,000 primary vaccinations have failed as a result of the hot weather and the additional exposure of the virus to high temperature en route from the East.

Septic Beards.—It is stated that a movement is contemplated to compel the dairymen of Los Angeles to remove their whiskers. Possibly the report is only the result of an effort to emphasize the fact that the very efficient and energetic bacteriologist of the Health Department is a woman.

Yellow Fever in Cuba.—Owing to the continued appearance of new cases of yellow fever, Governor Magoon has declared the districts of Cruces, Vanchula, Palmira, and Lajos, near Cienfuegos, to be an infected zone. Passenger trains running between Cruces and the other three towns will carry physicians, who will make inspections of the passengers en route. A detention camp will be established at Cruces, where nonimmunes will be subjected to five days' observation before they will be permitted to leave the infected zone.

The Fish Diet Theory of Leprosy.—Mr. Jonathan Hutchinson claims to have found, in the course of a recent trip of investigation through the Rhone valley, additional support of his theory that leprosy originates in districts in which badly cured fish forms an article of food. Cases of the disease occurring in this region were at first thought to be in contravention to this view, but on inquiry into

the habits of the peasants it was found that even in the remote regions imported fish of poor quality was used during the winter and spring.

Death of Rashid, the Leper.—It is reported that George Rashid, the Syrian leper who several months ago was driven from various cities in the East because of the dread of his disease inspired in the populace, has died in a shanty near Clarksburg, W. Va., where he had been living under the care of a nurse.

Margaret J. Plant Pavilion Dedicated.—The new Margaret J. Plant Pavilion, occupying the southeast corner of the St. Luke's Hospital property, was dedicated on October 18 by Bishop Coadjutor David H. Greer, in the presence of the Medical Board and a distinguished company of clergy and laity. The new building, which is devoted entirely to the care of private patients, comprises all the most recent features of hospital construction and was erected at a cost of $500,000, presented by Mrs. Margaret J. Plant.

Berne Conference.—The international conference recently held at Berne for the purpose of regulating the employment of women at night and the use of white phosphorus in the manufacture of matches was attended by delegates from fourteen countries. A convention to prohibit the use, importation or sale of matches made with white phosphorus was signed by the representatives of the following seven States: Denmark, France, Germany, Holland, Italy, Luxembourg, and Switzerland. A convention was also signed whereby a minimum period of eleven hours' repose for women is insured. This period includes the time from 10 P.M. to 5 A.M. to women employed in all industrial enterprises where there are more than ten workers of both sexes. The convention will take effect in two years' time.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga and amounting to about $180, will be made on July 14, 1907, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in Medicine, but cannot have been published. They must be typewritten and must be received by the Secretary of the college, Dr. Thomas R. Neilson, on or before May 1, 1907. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

A Crowded Havana Asylum.—Governor Magoon, in a visit paid to the National Insane Asylum at Havana on Sunday last, found 1,660 persons of both sexes crowded into filthy and dilapidated buildings with a capacity for 400 persons only. They were sleeping on broken cots, relics of the last American occupation. The Cuban Congress made an appropriation to enlarge the asylum, but the money was never expended, and the conditions today are very little better than under Spanish control. Governor Magoon will take steps to erect additional buildings and remedy the abuses.

To Chess Players.—The Tri-State Chess Association, an association of over four hundred chess players, most of whom reside in the Mississippi Valley, is arranging a correspondence match at chess, the Doctors *vs.* the Laity. It is desired to have physicians from every section of the United States engage in this match, and every chess-loving physician is urged to become a consultant. The match will begin early in November, entries being accepted until January 1. There is no fee attached to the match. All who will play are urged to send name and address to the president, Dr. Van Nuys, Lorain, Ohio.

A Baby of Unusual Size.—The birth was reported last week, from the lower East Side, of an infant weighing twenty-two pounds. This was the fifth arrival of a family whose previous members are said to have weighed at birth, respectively, in order, ten, fifteen, sixteen, and eighteen pounds.

The Wesley M. Carpenter Lecture.—Dr. Harvey Cushing of Baltimore delivered this lecture before the New York Academy of Medicine at its stated meeting, held October 18. The lecture was entitled "A Discussion of Some Early and Some Late Complications of Cranial Injuries and Their Treatment; Based on the Histories of Three Illustrative Cases." The cases were illustrated by lantern-slide projections.

Portrait of the Late Dr. Paul F. Munde.—At a meeting of the Academy of Medicine on October 18, Dr. A. Jacobi presented to the academy on behalf of Mrs. Mundé a portrait of the late Dr. Paul F. Mundé painted by herself. The gift was accepted with appropriate remarks in behalf of the academy by the President, Dr. Charles L. Dana.

Medical Society of the County of New York.—At the one hundred and first annual meeting of this society, held at the Academy of Medicine on October 22, the following were elected as officers: *President,* Dr. Walter Lester Carr; *First Vice-President,* Dr. H. Seymour Houghton; *Second Vice-President,* Dr. William Hallock Park; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson.

Obituary Notes.—Dr. Alphonse B. Brown of Newburyport, Mass., died suddenly on October 18. He was operated upon for appendicitis two weeks ago and was apparently recovering his strength. He was born in Dover, N. H., was graduated from Yale College and from the Harvard Medical School. After graduating from Yale Dr. Brown joined the Peary relief expedition to the Arctic.

Dr. Charles Samuel Williamson of Brooklyn died at Rainbow Lake, in the Adirondacks, after a short illness, on October 20. He was born in Brooklyn thirty-seven years ago and was a graduate of the College of Physicians and Surgeons of New York and the University of Berlin. He had practised medicine in Brooklyn for about twelve years.

Dr. P. W. Allen of Hebron, Va., died on October 8, in his sixty-sixth year. After serving with distinction in the Civil War he entered the Medical College of Virginia, from which he was graduated in 1868. He then returned to his native county and for twenty years practised, together with his father, Dr. E. H. Allen. Since the latter's death he had a very extensive practice in Nottoway, Dinwiddie, and Amelia counties.

Dr. Max Hempel of St. Louis died on October 9, at the age of forty-three years. He was born in Dresden, and after coming to this country he in 1882 and 1883 attended the St. Louis Medical School, and the medical department of Washington University from 1898 to 1901. He was a member of the St. Louis Medical Association, the American Medical Association, and numerous German societies.

The First Harvey Society Lecture.

The first of this winter's lectures of the Harvey Society was delivered at the New York Academy of Medicine on Saturday evening last in the presence of a very large audience. The lecturer was Prof. A. E. Wright of England, who took for his subject "Therapeutic Inoculations with Bacterial Vaccines." The speaker began by enumerating the different methods used in combating bacterial infections.

There was no denying the value of the expectant method in the treatment of many bacterial infections. And yet this method had its limitations. In plague and in Malta fever, for example, it did little or nothing. The expectant method did nothing, furthermore, in localized bacterial diseases such as lupus, tuberculous glands, etc. Treatment by means of chemical antiseptics had had its vogue. It was often forgotten that any agent strong enough to kill the invading microorganisms was very liable to injure or destroy the defensive mechanism of the body. Treatment by extirpation was formerly the great remedy proposed by the surgeon. But it was found that operations on tuberculous glands or on an infected joint were sometimes followed by acute general infections, or by acute recurrences. Treatment by the determination of lymph and blood to the infected region was still widely employed, though this also was of limited application. The Finsen light probably acted by determining a flow of lymph to the part, and Bier's passive congestion treatment would come under this head. In order that treatment along these lines be effective it had been found that the body fluids, the blood and lymph, must be rich in protective substances, *i.e.* in antibodies. Treatment by Koch's old tuberculin along the principles first laid down by Koch had also been discarded because of the many failures. Finally there was treatment by antisera, inaugurated by von Behring.

Professor Wright then discussed briefly the antibacterial substances occurring in the blood, namely the agglutinins, bactericidal substances, bacteriolytic substances, and opsonins. He described the latter as substances acting on the bacteria and changing them in some way so that the bacteria were more readily taken up by the phagocytic leucocytes than were bacteria not so treated. The change in the blood of a patient following the inoculation with bacteria was illustrated by the following example: A patient who for years had suffered from a severe form of acne, *i.e.* infection with staphylococcus, was inoculated several times with dead cultures of staphylococci. After a time the acne was completely cured. When the patient was almost well his blood was examined by mixing one volume of his blood serum with one volume of fresh washed human leucocytes and one volume of an emulsion of staphylococci. On making smears of this mixture it was found that each leucocyte had engulfed on an average 26 cocci. The same test, when a normal person's serum was used, showed only 13 cocci per leucocyte. The inoculations of staphylococci had therefore raised the opsonic power of the patient's blood. Compared with the normal individual, and regarding that as 1, the patient's opsonic index was 2. The researches of Wright and his pupils had shown that the change was one of the serum, and not of the leucocytes.

"It has been found that the inoculation of a bacterial culture is followed at first by a decrease in the opsonic power of the inoculated person's blood. This decrease is then succeeded by an increase to a point greater than the original. The drop is called the 'negative phase' and the rise is the 'positive phase.' If too large a dose of culture is inoculated the negative phase is very marked and the positive phase is insufficient to restore the opsonic strength to the original point. If there are several such inoculations or if the inoculations are given at improper intervals of time there is an accumulation in the direction of the negative phase. The end result is a lower opsonic index than was present originally. If the inoculations are well planned as to dosage and intervals of time there is an accumulation in the positive phase. The end result is a higher opsonic index than was originally present. This is what we strive to achieve in our so-called 'vaccine treatment,' and this is what one finds quite difficult.

"By examining at frequent intervals the blood of a boy suffering from hip-disease some interesting facts were brought out. The boy had not walked for some time prior to the first blood examination, and was carried into the laboratory. Directly after the blood was drawn for the first test the child was made to walk briskly about the laboratory for about fifteen minutes. Then the blood was tested again, and it was found that there had been a sharp drop in the opsonic index. Then six other examinations were made at twenty-minute intervals, and these showed that the sharp drop ('negative phase') was succeeded by a rise, and that after several more slight changes the blood showed a slightly higher index than originally. This experiment, then, showed that the exercise which the boy had undergone had resulted in an 'autoinoculation,' *i.e.* the boy's system had been flooded with some tubercle virus. If tuberculous patients are allowed to rest quietly in bed they have no autoinoculations and their opsonic power remains low. They therefore do not do well. If they are judiciously exercised, however, they become autoinoculated and increase their opsonic index. These are the cases that do well. The same autoinoculations can be brought about by other means, *e.g.* massaging a joint or a mass of glands. With localized lesions, especially if they are small, there is little or no autoinoculation. The tendency of such cases is therefore not to get well.

"Cases of tuberculous adenitis, when seen very early, almost always have a low opsonic index, *i.e.* there is no autoinoculation. Later, when there is much involvement and more absorption of tuberculous poison, there is a high index. The index in beginning phthisis is also low. The good that is often done by simple surgical interference is probably due to an increased opsonic power produced by the autoinoculation brought about. After, for example, paracentesis of the abdomen in cases of tuberculous peritonitis, there is almost always a rise of opsonic power. Disturbances of this sort, however, may be too severe, so that we often see such operations followed by an increased severity of the disease. The same is true of massage of the involved parts. These dangers are avoided in artificial inoculation, and this then is what we now employ."

Professor Wright then gave histories of a number of cases he had treated. An interesting case was one of streptococcus pyemia, in which the patient had done poorly under antistreptococcus serum. The organism was cultivated out of the patient's blood and she was then treated with appropriate doses of these cultures. Improvement began with the increase of the opsonic power and continued to complete recovery. There was no necessary agreement between height of fever and opsonic index.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE NEW SESSION—INTRODUCTORY LECTURES—MEDICAL EXHIBITION.

LONDON, October 5, 1906.

THE winter session has begun and the schools are again at work, most of them having opened on Monday, though some delayed until Tuesday. The interest of the introductory lectures still maintains itself, although the London Hospital and Bart's are among those that have discarded the old-time mode of beginning the medical year. Charing Cross Hospital was again easily first in anticipation by making the Huxley lecture the introductory and securing Professor Pawlow to deliver it, thus drawing a very distinguished audience. The realization of the expected pleasure was in some cases feeble, as the Professor spoke in German and we are not all linguists. He took for his subject the "Scientific Investigation of the Psychical Faculties or Processes in the Higher Animals"—not exactly an elementary study, but rather, as he remarked, so exceptional that it could not possibly be subjected to successful analysis, for it was prepared by laboratory methods. Dealing with the highest vital phenomena, science could not escape misconception, and therefore opposition. Science need only attempt to determine the connection between the responsive faculty of the living organism and given natural phenomena. He described how nerves responded not only to direct but to indirect stimuli and developed a faculty of discrimination, and he held that the introduction of the idea of conditioned reflexes into physiology was justifiable. The investigation of these reflexes was of great importance to the physiology of the higher central nervous system. Hitherto ideas borrowed from psychology had been employed in physiology, but should now be discarded. Physiology had yet to attack problems which so far had perplexed humanity, and immense advantages would ensue when investigators treated them as other natural objects and the human mind contemplated itself from without instead of from within.

Sir A. Rücker proposed the vote of thanks, which was seconded by Professor Starling, who remarked that Professor Pawlow had shown how to experiment on living animals without anesthetics or causing pain. Moreover, his work had caused the text-books of physiology to be rewritten in the last ten years.

At King's College Mr. Pridgin Teale gave a retrospective lecture. It was, he said, fifty-four years ago that he entered for his first session, and he was one of a small number of living men who had taken part in the greatest revolution of medical science and surgical practice the world has known. He remembered when the school theater was used for both operations and post mortems and Miss Nightingale went as nurse to the Crimea. He passed on to describe many advances as illustrated at the Leeds Infirmary, to which he became surgeon twenty-two years ago, and the part taken by Kings' men in medical progress. Referring to the removal, he said he had looked over the plans for the new buildings and greatly admired the way in which every possible requirement was provided for. He believed the new hospital would be one of the most perfect in the Kingdom. The four hundred beds arranged for could be increased to six hundred. It is expected the building will be begun early next year.

At University College the Dean reported that there were 242 medical students, 91 of them new entries. Professor R. J. Godlee gave the address, which was on the "Past, Present, and Future of the Medical School." The college, he said had been at work for seventy years, and it now had as perfect a hospital as it was possible to get on a limited site in the center of a great population. The school of advanced medical studies in connection with the university was an experiment to be watched with intense interest. Now that the new hospital is complete, there are 277 beds available for use. The new nurses' home and the house for maternity students are to be ready for occupation next year.

At the Middlesex Hospital, the Lord Mayor, accompanied by the Lady Mayoress and the Sheriffs, attended in state the opening of the school. There was a large attendance, including the two Presidents of the Royal Colleges of Physicians and Surgeons, both of whom are connected with this hospital. The address was given by Dr. Campbell Thomson, who dealt with "Hospitals and the Public," pointing out how many people failed to see that a hospital was not restricted in usefulness by the locality it occupied, that the proper persons to receive its benefits were the suffering poor. The correlation of the different forms of medical relief for the poor was urged as of great importance. People should be encouraged to take more interest in hospitals, and then they would see that nothing that skill and money could do was spared to promote the comfort and welfare of patients, and that the "horrors of hospitals" had no existence outside the imaginations of persons who had never visited one. There was danger in the apathy of the people lest a financial crash might lead to a call for aid from the rates. Medical education, he held, must look to endowments. At this school Mr. Henry Morris had started with £1,000, and no doubt other gifts would follow. Dr. Thomson also referred to the cancer research at this hospital.

The Lord Mayor delivered the prizes and expressed great interest in hospitals, and this in particular as one he had long watched for. He sincerely hoped no more would be heard about hospitals going on the rates. He trusted that would never happen in this country.

At St. Mary's Hospital Dr. Alcock was the lecturer and took as his subject the "Theory and Practice of Medical Education." He managed to offer a novelty in regard to this well-worn theme by collecting from practitioners in town and country lists of cases attended. He tabulated 500 such cases by way of showing what actual practice consisted of. From these he deduced that the preliminary and intermediate sciences were of great use indirectly, less so directly. It was not, he said, the actual facts of biology, for example, that were used, but the scientific methods, and therefore these subjects should, he thought, be taught in a different way from the strictly professional branches of study. The opinions of the practitioners who had been asked were against shortening the curriculum or lowering the standard of science. Taking these opinions and the lists of cases, he concluded that better results might be obtained by a rearrangement of the curriculum—the elementary courses being completed in two years and the third year being given to advanced study in one of these subjects. The advantages offered at St. Mary's by the fully equipped laboratories were also referred to.

At the Leeds University School Sir J. Crichton-Browne distributed the prizes and delivered the address. Though alive to the example Germany set in providing research laboratories under professional directors, he did not share the wholesale admiration of everything educational in that country, nor timorous forebodings of friendly rivalry. But England had been remiss, and her neglect of medical education amazing. To keep it up to the level of other countries, assistance must come from the State or from the overflow of plethoric private coffers. Sir James then passed to a spirited attack on neomaterialism. He said many physiologists aimed at bringing their science into line with physial sciences and showing that physiological phenomena were but complex problems of a physical or chemical nature, but to do this they must deprive their science of its distinctive character; for if it was the sum of scientific knowledge concerning living beings, it must cease to be physiology when it denied the existence of life and reduced what had hitherto been regarded as vital functions to phenomena of an inorganic nature. It was admitted that many aspects of living things which at present defy exact expression in accordance with physical and chemical conceptions—nay, it was admitted, that our present knowledge of living tissues, complicated as they are, was extremely limited; and yet every little advance in physiological knowledge was made a pretext for proclaiming the final dethronement of life and the absolute dominion of brute force over vast regions of which it was incapable of taking effective possession. The discrepancies between living and nonliving phenomena had not been explained away. Behind every going concern and working mechanism, like a watch, there was the life that had made and started it and wound it up, and without which it would not exist or go; and yet they were asked to believe that the most intricate and marvelous of all mechanisms, the human body, had no life either in it or behind it. The new materialists, having dissipated the phantom of vitality, left us plants and animals, more or less complicated arrangements of proteid substances responding in a very simple way to the ordinary physical forces we see around us. They left us the brain, a mass of gluelike substance, nine-tenths water, with a little phosphorus thrown in, traversed by waves of force and nothing more. They left us man—a motorcar, self-made and self-started, with no passengers and no chauffeur, moved by a series

of explosions or redistribution of energy, and rushing on to inevitable destruction. The wild speculations of these neomaterialists were not in accordance with the sobriety of medical philosophy as hitherto understood. True, it seemed that in their case "knowledge comes, but wisdom lingers." But wisdom was the best product of a university. Whatever theoretical tenets they might adopt, whatever physiological system, they would, when they found themselves as practitioners at the bedside, become ardent vitalists. Their aim and object in their career would be to keep alive that mysterious spark that glowed in their patient, an emanation, as it were, of that vital activity that gave warmth and movement to the thin and fragile film of organic matter that was spread over the surface of the earth. Their object and aim would be to obviate the tendency to death in the pursuit of that mission, and all diseases were included in the tendency to death.

The lecturer then spoke of the lives thrown away by preventable diseases and the hope of further reduction in this waste.

At the London Medical School for Women Professor Byers of Belfast delivered the address. He pointed out the work which was ready for educated women with trained powers. To those who had qualified, he said, many public functions offered them a scope for their energies, *e.g.*, inspection and supervision of school children. The London County Council had given six out of twenty appointments as assistant medical officers to former students of the School for Women, and their duties included the inspection of school buildings and reporting on the health of the scholars. He warned the students that they were entering the most exacting profession, but none was more useful or unselfish, and concluded by urging them to practise "their calling as much as possible free from every trace of narrowness, bigotry, or superstition; to be tolerant of the opinions of all races and sects, ever keeping by them the glorious example of Him who went about doing good."

Dr. Donald MacAlister, President of the General Medical Council, went to Manchester and delivered the address, which he devoted to the powers and work of the council over which he presides. He pointed out precisely the limitations of the council and showed how unreasonable are the expectations of some persons who blame it for not doing things it is impossible for it to do. Many sober critics of the council might advantageously study this address, though I cannot go so far as to assert that the council has done all it might do.

Besides the introductories there have been dinners at the several schools, and where no special lectures were given these reunions have assumed additional importance. Some other receptions have also been included in the opening ceremonies.

The *British and Colonial Druggist* is to be congratulated on the second medical exhibition organized by its proprietors and staff. It opened on Monday and has been largely attended all the week. It closes tomorrow. This exhibition has been strictly confined to the medical profession. All the latest novelties in medicine, hygiene, dietetics, appliances, and so on, were on view. A handsome reception room, where light refreshments could be had and where first-class music was provided, added to the attractions, and it was an admirable feature that the public were rigidly excluded. There were more than one hundred stands of exhibitors, and they could be examined with the attention they deserved.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CLIMATIC TREATMENT OF DYSENTERY—A NEW GOVERNMENT HOSPITAL AT BAGUIO—SUBSIDENCE OF THE CHOLERA—A CHOLERA SERUM—QUARANTINE—GONGOSA—THE YAWS SPIROCHETE—THE PROTECTIVE VALUE OF VACCINATION.

MANILA, September 1, 1906.

In the annual report of the Bureau of Health for the fiscal year ended June 30, 1906, the fact is mentioned that of the dysentery cases treated in the Government Sanitarium at Baguio, which is at an elevation of 4,716 feet above sea level, it is interesting to note that 80 per cent. recovered. When it is remembered that the cases of dysentery treated at Baguio are recruited principally from cases which have resisted all medical treatment in the Civil Hospital at Manila, the important point is forcibly brought out that climate is a most important factor in the treatment of this disease. The 20 per cent. that were not cured showed a marked improvement in condition. The average period of treatment was sixty-five days.

In this connection it is interesting to observe that the Government intends erecting a modern hospital at Baguio. The building will cover, roughly, an area of 200 by 75 feet, and will consist of a central portion with a wing on each side. The greater portion will be one story only; that portion immediately above the center will have two stories, and will be divided into six private rooms. The central portion of the building will be used for administration purposes. The wings will have a capacity of fifteen beds each, and will be arranged on the ward plan. An operating room, isolating quarters, and all other provisions made in modern hospitals will be provided. The building is to be erected on a high knoll, from which a most beautiful view may be obtained to the east, south, and west.

There has been another marked diminution in the number of cholera cases for the past two weeks. For the first half of August there were reported 131 cases and 125 deaths in Manila, and 1,064 cases, with 814 deaths, in the provinces; while, during the last half of the month, there were 74 cases, with 67 deaths, in Manila, and 576 cases, with 499 deaths, in the provinces. The mortality is also gradually being lowered, and now has reached something under 60 per cent. During the past week Manila has been almost entirely free from cholera, with the exception of a few cases which occurred in Bilibid Prison. It seems almost impossible to keep this prison free from the disease. The infection, in all probability, is correctly attributed to the prisoners who are permitted to work outside, thereby being enabled to smuggle food into the prison. It does not seem possible that it could be introduced in any other way. When it is remembered that there are over 3,000 persons crowded into an area usually occupied by a small city block, it will be seen that so long as there is one case of cholera in the prison it is a grave menace to the institution, because an epidemic of large proportions might easily result.

Dr. Dernier, the French bacteriologist, of whom mention has already been made, is still conducting his experiments in the use of a curative cholera serum in the treatment of cholera cases. Owing to his work not yet having been completed, it is not possible to give a scientific report of his results, but it may be stated that his serum, made from dead cholera bacilli, is giving unsatisfactory results. He has discontinued its use and is now engaged in injecting a serum which is made from living vibrios. In all, he has treated twenty cases, of which fourteen died. Of the six to be accounted for, several are still in a precarious condition.

Still further modifications have been made in the outgoing quarantine which has been imposed upon vessels leaving cholera infected ports in the Philippines, since the outbreak of cholera, August, 1905. The new order provides that interisland vessels whose first port of call is one of the ports at which a regular surgeon of the United States Army is stationed, are permitted to proceed direct to such port, and complete the detention period of quarantine at port of arrival. In this way the period occupied by the voyage is in reality deducted from the quarantine, thus facilitating business very much.

Dr. E. R. Stitt, of the United States Navy, has just returned from Guam, where he went for the purpose of making a study of one of the diseases with which the natives of that island are afflicted, and which has been the subject of frequent comment in the lay journals. Dr. Stitt reports that the disease ordinarily referred to as being peculiar to Guam is gongosa, which is not only found in Guam, but in the Fiji Islands. It is more prevalent during certain seasons of the year, and he was not able to observe any cases in their incipiency. However, from reliable testimony he was informed that the disease usually commenced in much the same manner as diphtheria, the first symptom observed being a whitish membrane upon the tonsils and fauces. This has a corroding action and gradually destroys the tonsils, uvula, and soft palate, and then gradually eats its way through the hard palate and later attacks the vomer. In some cases the disease travels up the tear ducts and then destroys the eyes. A great many microscopical examinations have been made and scrapings taken from the seat of the disease, but so far nothing characteristic has been found. Dr. Stitt has brought with him a considerable amount of material, which he hopes to work up later in the laboratory. The therapeutic test for syphilis has been applied in a number of cases without any appreciable result, and from the appearance of the disease it is not believed to be syphilis.

Dr. Stitt also reports that he found the same spirochete in cases of yaws at Guam as are reported by Celli in the cases of yaws at Ceylon.

Another most striking illustration of the value of vaccination against smallpox is shown by the figures from two of the provinces which have recently been vaccinated. In the province of Cebú for many years past nearly 2,000 persons

annually lost their lives from smallpox, while during the past year, during which the vaccination of the province has been going on, only about 200 deaths have occurred. In the province of Cavite, in which the vaccination was completed about a year ago, and in which province for a number of years past 750 deaths occurred annually from smallpox, not a single death from smallpox has been reported since the province was vaccinated.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 11, 1906.

Observations in One Thousand Operations.—F. B. Sprague analyzes the records of his personal cases. He prefers ether for an anesthetic. The tonsils, if demanding removal, are left to the last, unless they are very large and prevent free access to the nasopharynx. Immediately after operation an application of glycerite of tannic acid is made to the denuded areas of the fascia and pharynx. In general the paper covers only familiar ground.

Acute and Chronic Indigestion.—J. B. Deaver refers to various conditions, the expression of which is either acute or chronic disturbances of digestion, and underlying which some lesion may be present which calls for surgical intervention. Or there may be abnormalities of the circulating and nervous symptoms. When patients complain of pain following the ingestion of food, vomiting, hematemesis, with or without anorexia, are pale and weak, and have lost much flesh and experience relief by restricted diet and rest in bed, this must mean in almost every instance organic disease of the stomach. Deaver does not believe that modern methods of examining stomach contents are of much service in making a differential diagnosis between functional and organic disease. Careful physical examination of the abdomen and other regions of the body with a reliable history of the patient is of much more value than chemical examinations. The great disease which is liable to be overlooked in an attack of so-called acute indigestion is appendicitis. In every such attack careful abdominal examination should be made. In this disease the sequence of symptoms is nearly pathognomonic, pain, then vomiting, and lastly localized tenderness. In intestinal obstruction the same caution is called for. Frequently the acute pain of strangulation precedes the vomiting by a number of hours. A careful search of the hernial rings will frequently reveal a strangulated hernia. Diseases of the biliary passages are another prolific cause of acute dyspepsia. In regard to chronic indigestion Deaver believes that if a patients complain of persistent or recurrent indigestion, which is relieved not at all or only temporarily by medical measures, we are surely justified in offering them as a solution of their structural disorders, some form of mechanical remedy; in short, some form of operation.

New York Medical Journal, October 13, 1906.

X-Rays in Neuritis.—A preliminary report on this field of radiotherapy is made by J. H. Comroe, who records his results in six cases, some acute and some chronic. He presents the following conclusions: (1) The *x*-ray should be employed in the treatment of neuritis only after all other judicious methods of therapy have failed. (2) The exposure should be directed over as wide an area as may be safe, and frequently repeated in the beginning. (3) The strength of the current and duration of the exposure should, as a rule, be in direct ratio to the approximate distance of the affected nerve structures from the cutaneous surface overlying them. Idiosyncrasies must be carefully sought. (4) Relief if obtained usually makes its appearance early in the treatment. (5) Obstinate cases should receive "tonic" treatment with a medium tube for some time after the patient has been apparently cured so as to further assure permanency. (6) Postoperative treatment in nerve resections, as shown in Case IV (and also by Faber), is highly recommended.

Hydrotherapeutic Treatment of Chronic Rheumatism.—J. J. Levy has obtained much satisfaction from the following plan of treatment: (1) The patient is given an electric-light bath, temperature, 150° F., duration twenty minutes, to be followed by a circular douche 90° F., duration one minute; this is followed by a Scotch douche to the affected joints, and this in turn is followed by a general massage with special attention to the affected joints or muscles. Three treatments a week are usually sufficient for these cases. The Scotch douche referred to consists in the alternate application of hot and cold water. The author styles it "the douche of thermic contrasts." His apparatus has three tubes placed side by side, one for live steam, one for cold water, and the third gives any desired temperature, as the thermometer is in contact with the mixing chamber. He usually employs steam and cold water for the Scotch douche, and by means of the rapid alternation in the application of live steam and cold water to the affected parts, a most profound local effect is produced, and a marked hydrotherapeutical reaction is brought about. The value of this douche consists in the combination of thermic and mechanical stimulation, the mechanical effect is produced, because the water comes out of the tubes under pressure which can be increased as desired, while the marked thermic stimulation is due to the tremendous difference in the temperature of cold water and steam. The increase of vital activity brought about by the reaction following the Scotch douche becomes of great value in restoring the functions of diseased parts. On account of the improved circulation absorption of the deposits in the joints is brought about.

Urethral Diverticulum and Cul-de-Sacs.—N. E. Aronstamm describes two forms of these urethral peculiarities: (1) The diverticulum, a short, narrow, collapsible pocket opening into the urethral canal, from one-quarter to one-half an inch in length, of the caliber of a knitting needle, unyielding and nondilatable; and (2) the cul-de-sac proper, a larger, longer, and more distended pouch stopping abruptly, or, rather, terminating blindly in the mucous lining of the urethra, seldom exceeding one inch in length, and somewhat larger in caliber than the preceding one. Both of these varieties are congenital anomalies, rarely found further down than the first two inches of the anterior urethra, and are in most instances situated on the floor of the canal, thus distinguishing them from enlarged and patulous urethral follicles which are commonly located in the roof of the urethra, in proximity to the fossa navicularis. The author describes the mode of formation of these structures from the embryological standpoint. Their symptoms simulate those of a mild urethritis. Painful micturition and urinary tenesmus may be prominent features. If they become implicated in a gonococcic process, various strictures may form. The first principle of treatment should be to locate the exact site of the difficulty. This can generally be done with the urethroscope, small sound or probe, or fine olivary bougie. The lacunar fold is then slit open with a small knife or tenotome throughout its entire extent to the very bottom of the urethral mucosa. Or, after the site of the channel or sac has been located, a urethrotome may be introduced, and by a sweep of the delicate blade the pocket is divided. Local anesthesia usually suffices to accomplish this result. As soon as the fold of mucous membrane has been severed, this should be immediately followed by the insertion of sounds in ascending sizes until the largest can be conveniently passed, and left *in situ* for at least ten minutes each time. This must be continued for a week or ten days to prevent the too premature closure or healing of the divided edges or subsequent fibrous contraction, which may ultimately lead to stricture formation. Rarely is the fold of mucous membrane so extensive as to require ablation or removal *in toto*. The two lateral bands eventually become atrophied and at a level with the urethral canal. Another method that may be utilized consists in the dilatation of the urethra either by means of a urethral dilator, or, what is still simpler, with an ordinary dressing forceps gently introduced and expanded to its utmost limit, provided, however, that the cul-de-sac is not situated too far posteriorly, severing the band by means of small scissors, and then proceeding in the manner already delineated.

Journal of the American Medical Association, October 20, 1906.

Simultaneous Nonrelated Tumors in a Mouse.—E. E. Tyzzer reports the finding in an old uninoculated mouse, kept for breeding purposes in the laboratory, of two nonrelated primary tumors, an adenocarcinoma of the lung and an adenoma of the kidney. Inoculation of other mice with the lung tumor resulted negatively. This is perhaps accounted for by the fact that it contained no cells in mitosis. Nuclear inclusions that were found are not regarded as specific, since they are occasionally found in the tissues of other mice.

Sodium Citrate as a Modifier of Cow's Milk.—The chemical action of sodium citrate as a modifier of cow's milk is discussed at some length by J. W. England,

who gives it as his opinion that sodium citrate, which is a neutral salt, has no decomposing action on casein calcium in the cold, and that, when the citrated milk is brought in contact with the gastric juice, the sodium citrate is decomposed into sodium chloride and free citric acid; and that the sodium chloride has more important physical and chemical properties in the digestion of cow's milk than has hitherto been suspected. He considers it very doubtful whether the free citric acid has any more important therapeutic value than the hydrochloric acid of the gastric juice stimulated in production by the presence of the sodium chloride. The article is illustrated.

Publicity as a Factor in Venereal Prophylaxis.—P. A. Morrow declares that the concealment of facts regarding venereal diseases is a factor in perpetuating the evils attending them. The value of publicity in the suppression of evils has been amply demonstrated of late, but the venereal evil furnishes the most conspicuous example of an evil that flourishes in darkness and owes its power for mischief to the obscurity to which it has been relegated by traditional prejudice. Publicity here is desirable, he says, and is absolutely indispensable to the success of plans for prophylaxis. To the question, is publicity practicable, he answers that it is, and that the sentiment that forbids the open discussion of the subject has no place in the counsels of preventive medicine. Though the newspapers are not available, physicians can work with tracts, pamphlets, conferences, lectures, meetings of medical societies to which the public is invited. Another valuable agency would be a journal of popular medicine, devoted to the study and prevention of all communicable diseases, especially those spread in the ordinary relations of social life. Such a one has already been projected. He believes the present a favorable time to dispel the indifference of the public regarding this evil and to bring about reform.

Pleuritic Exudates in Children.—M. Germann describes pleuritic effusions as they occur in childhood. She finds this condition rather common before the fifth year of life and rather more frequent on the right than on the left side. The symptoms are often acute in onset and liable to be taken for pneumonia, which frequently coexists. In the serous form the prognosis is generally good, and if there be no serious displacement or disturbance of respiration or circulation an expectant treatment may be all that is required; otherwise aspiration is advisable. Empyema, however, seldom recovers without surgical treatment. She favors rib resection in these cases and describes Dr. J. D. Bryant's method of performing thoracotomy. Four case histories are given; in three of them thoracotomy was performed.

The X-Rays in Leukemia and Hodgkin's Disease.—A. H. Roth reports two cases treated with the *x*-rays: one of Hodgkin's disease, in which the relief of symptoms was obtained, though they probably may recur unless the treatment is continued, and one of splenomyelogenous leukemia, in which the continued application of the rays for over a year has brought the blood down to the normal and largely reduced the splenic enlargement. Arsenic used as an adjunct to the treatment seemed to be of benefit. The first effect of *x*-ray treatment was to increase the number of leucocytes in the general circulation. This was accompaied by a large increase of degenerate cells, most of them disintegrating myelocytes. No toxic symptoms have developed in the patient, and though the blood count has remained normal for two months, the continued use of the *x*-ray at intervals is advised to prevent possible recurrence. The application was made in the leukemic case over the spleen and long bones with a hard tube at a distance of ten inches from the anode, the applications lasting from seven to fifteen minutes. In the case of Hodgkin's disease the *x*-ray treatment was made over the enlarged glands.

Streptococcus Leptomeningitis.—E. E. Southard and R. R. Stratton report a series of cases of leptomeningitis from streptococcus infection, the studies being given in detail with autopsy results. The lesions reported do not differ in any constant features from those reported by Southard and Keene in 1905 for pneumococcus. The two organisms, in their action on tissues, would apparently fall in the same group. The durations in the streptococcus cases were rather greater than in the pneumococcus ones, but the microscopic findings were very much alike in each. The vascular lesions may serve to distinguish the pneumococcus-streptococcus cases from those due to the meningococcus, but it would be less easy so to utilize them in the differentiation from the tuberculous cases. It is rare, the authors remark, to find any simple lesions in acute leptomeningitis that are necessarily incurable, and they suggest that it is probable that in many cases the patients die of toxemia, which may vary with the extent of the exudate. They say, however, that the amount of exudate observed at an autopsy may mislead the observers as to the amount of the toxemia, as large portions of the pia may be sterile while other parts may contain multiplying organisms. Differential studies of the exudate in different portions are necessary to reveal the conditions, and such studies may be of clinical importance. The authors remark that lung lesions have probably been overestimated as producing meningitis, and that the streptococcus cases seem to be more pronouncedly cerebral, or primary from the start, than are the pneumococcal or staphylococcus cases. The early glioses observed in several of the cases here reported are of general and clinical importance, and will be more fully noted in a future paper.

The Lancet, October 6, 1906.

Fracture of the Sternum.—The patient of J. F. Alexander, a man of sixty years, fell from a loaded wagon eight feet to the ground, striking on his head and being somewhat stunned. On recovering consciousness, he picked himself up and went home, remaining in bed three days, as he "felt stiff when he moved." He then consulted Dr. A., who found a contused area covering nearly the whole of the front of the thorax and a ridge crossing the chest transversely at the level of the second intercostal space. A diagnosis was made of a transverse fracture of the sterum just above the level of the attachment of the third pair of costal cartilages, and the ridge was caused by the slipping upward and forward of the lower fragment of the sternum, with the attached third pair of ribs, on to the upper fragment. The third rib on the right side was also fractured close to its junction with the costal cartilage. On making the patient lie down on a flat couch, without a pillow under his head, the displacement was easily reduced, but returned at once when he got up. He was sent home and told to lie on a hard mattress flat on his back, and while in this position, with the displacement reduced, the chest was firmly strapped. This at once relieved all pain, and within three weeks the fracture had united firmly in a good position without the formation of much callus. The author considers the case remarkable, in that, apart from the actual injury, symptoms were wanting. There was no cough, no hemoptysis, and no dyspnea. Some observations are added on the mechanics and general features of sternal fractures.

Notes on Purin-Free Diets.—W. A. Potts defines as purin bodies all those constructed on the base C_5N_4. Those of ordinary occurrence are uric acid, caffein, theobromin, xanthin, hypoxanthin, guanin, and adenin. They occur in meat, meat extracts, and especially glandular organs, as the pancreas and liver. Small amounts are found in many vegetables. A purin-free diet is of little value unless adequate attention is paid to other essential digestive factors. It is useless to abandon meat and live on high-flavored dishes with cream, etc. A graphic table is presented, showing the relative nutritive values in some sixteen common articles of diet. The purin-free list includes milk, cheese, white bread, macaroni, potatoes, apples, bananas, raisins, dates, and nuts. The plan indicated is advantageous in both chronic and acute maladies—functional as well as organic. Potts believes that functional disturbance is but a warning too often neglected, of the ultimate onset of organic disease. He then discusses methods of preparing and serving the various purin-free substances. Treatment along these lines avoids the liability of acute rheumatism which so often follows maladies, through the course of which stimulants and meat extracts are given. The author adds that "if our large hospitals, instead of constantly appealing for increased subscriptions and pandering to the popular taste, would devote their energies more to working out the best dietaries on these lines, and to instructing the public how to live healthily, their balance sheets would be more satisfactory and their needs for extension disappear.

The Injection of Antitoxin in Diphtheria by the Intravenous Method.—A. O. Bisson gives statistics of a certain hospital of 660 cases of diphtheria, with 92 deaths. The total mortality rate, therefore, was 13.94 per cent.; of 200 cases treated intravenously, the rate was 16.5 per cent. All very severe cases were chosen for intravenous treatment; hence, probably the higher rate. The author summarizes various papers which have appeared on this method of giving antitoxin and

describes the two methods, viz., by incision and direct puncture of a vein. In the former an anesthetic (ethyl chloride or chloroform) is required, but none in the latter. The bend of the elbow is the site usually chosen. The general impression derived from the paper is that the intravenous method possesses no advantages over the hypodermic as usually followed.

British Medical Journal, October 6, 1906.

The Wrong and Right Use of Milk in Certain Diseases of the Skin.—L. D. Bulkley summarizes the sequence of events occurring in the stomach during ordinary digestion, dwelling particularly on the "alkaline tide" which comes on after the organ has finished its active share in caring for an ordinary meal. This alkaline tide occurs at varying periods of time after the ingestion of food, dependent upon many circumstances; it may begin an hour or so after a very small amount of digestible food, or it may be delayed four, five, or even many more hours after a very heavy or unusually indigestible meal, or with very weak or sluggish digestion. This should constantly be borne in mind. It is only when this "alkaline tide" is perfectly secured and utilized that the method of giving milk to be recommended later can be successfully carried out. It is objectionable to take any food with the milk and to add egg or brandy to it. Harm may also result from the cream which has risen and been stirred in the milk, causing flakes, or by the slightest scum, caused by boiling the milk, and even by some foreign substance accidentally in the milk; these small solid particles, being incapable of immediate absorption, may cause the secretion of gastric juice, and so start the process of digestion. So also milk is taken too soon after a meal while the stomach is still acid. Of the skin diseases unfavorably affected by milk improperly taken, the author has found acne and eczema the most common.

Etiology and Treatment of Eczema.—Observations on these topics are made by G. Chambers. Combined constitutional and local measures give the best results. We should remember that the disease is a dermatitis with exposure of the rete mucosa. The three indications are to reduce the inflammation, soothe and protect the skin, especially the mucous layer, and to adopt measures to bring about the normal keratinization of the epidermis. It harms an acute eczema to wash it with plain water, because it removes the fibrinous exudate present. Consequently the skin, on drying, becomes less pliant and inclines to fissures. If, however, we apply a normal saline continuously, we find that it is soothing. The author says that in making the application cheese-cloth in 8 to 10 ply is moistened with the solution and applied to the patches. To prevent drying the moist dressing is covered with oiled silk. The dressing should be changed twice a day. In cases in which the eczema is impetiginous he adds boric acid in sufficient quantity to the normal saline solution to make about 1 in 60. At each change of dressing it is well to wash the affected parts with the solution. As soon as the skin, by its color, smoothness, the absence of crusts, etc., shows diminished inflammation and improved keratinization he discontinues the dressing and applies a soothing ointment such as Lassar's paste. Subsequently a mildly stimulating ointment may be required.

The Blood in Relation to Skin Diseases.—Some observations along this line have been made by T. Houston and J. C. Rankin. A low opsonic index was found in thirty-four cases of acne and other conditions from which a staphylococcus could be isolated. After inoculations according to the Wright method all these cases rapidly improved, though some relapsed. In lupus the opsonic index with tubercle bacilli varies. With a persistently low index neither the Finsen light nor any other treatment is likely to prove of service. If by inoculations the opsonic power can be raised, the improvement is marked. Some cases of lupus erythematosus have done well with the raising of the index followed by the Finsen light. The determination of delayed coagulability of the blood may give an important indication. In a case of erythematosus, on first giving Finsen treatment (a quarter of an hour exposure) the part treated rose up in huge blisters, requiring three weeks to heal. This again occurred after the second treatment. As the coagulation time was found to be prolonged, the patient was put on calcium lactate the day before treatment, with the result that she has had several exposures since with little or no blistering. Two other cases which showed much blistering had calcium lactate before treatment with great benefit. Another case which reacted severely to the light treatment and did not improve by taking lime salts was found to have a normal coagulation time. A young medical man who had tried a great number of applications for an edematous rash and tenderness coming on after shaving was quite well after taking calcium chloride for one week. In those dermatoses associated with serous effusions in which the coagulability of the blood is found diminished, the lime salts have been rapidly beneficial.

Berliner klinische Wochenschrift, October 1, 1906.

Toxic Edema.—Quincke, in discussing the forms of edema which occur in such conditions as pernicious anemia and the cachexia attending phthisis or malignant disease says that toxic edemas may be caused in any one of the following ways: Through the local action of the toxic substance either on the vessel walls, on the tissues themselves, or on both; through the toxic action on the nerves of the region in question, either centrally or in their course. These nerves may be vasomotor nerves affecting either the caliber of the vessel or the permeability of its wall, or they may be trophic nerves supplying the tissues themselves, or both varieties may be affected. Either the one or the other of these modes of causation may be observed clinically. The neurogenous variety is observed in cases of edema attending paralysis, and the migration of localized edemas sometimes observed may also be explained on this basis.

The Treatment of Trachoma with Radium.—Dinger praises highly this method of treatment and believes that it is preferable to any other. He used 5 mg. of radium bromide, which he applied first for one minute twice a week, increasing gradually up to five minutes. Later on the quantity of radium was doubled and the applications were made only once a week. No injurious by-effects were noted, and out of sixteen cases seven were cured and the others much improved. It was found that the younger patients improved more rapidly than the older ones, but even in very obstinate cases with pannus formation the lesions yield gradually and the patients are enabled to return to work. The painlessness and simplicity of the method are said to be very great advantages.

Münchener medizinische Wochenschrift, October 2, 1906.

The Treatment of Malignant Growths by Anesthetization.—Spiess has already published his views on the subject of the influence of anesthetization on inflammatory processes, and he now applies the same principles to the consideration of malignant growths. In inflammation he holds that the hyperemia is the result of sensory impulses emanating from the affected area, and he believes that malignant new growths are similarly maintained in a state of congestion. This increased blood supply is required for their abnormally rapid growth, and if this can be restricted the nutrition of the tumor will suffer to a considerable extent. A large number of experiments are described which were performed on mice obtained from Ehrlich's laboratory and presenting various types of malignant tumors. Into the centers of the tumors varying quantities of solutions of several anesthetic substances believed to be without antiseptic power were injected, with the result that in nearly all instances the growth of the tumor was influenced for the better, and in some cases an actual cure was secured. The author also details the results of similar experiments on inoperable malignant growths in human beings which, he says, were undertaken mainly for the purpose of ascertaining whether any undesirable effect was produced by the injection. He refrains, however, from any comment on these cases, but states that the subject is to be studied further in Czerny's new institute for cancer research at Heidelberg.

A Case of Pubiotomy in Private Practice.—Brenner was able successfully to terminate the labor of a twenty-four-year-old primipara with a moderately flat pelvis and a fetus two weeks overdue by resorting to pubiotomy. The fetal head was unusually large and did not mold well, so that attempts to deliver with forceps failed and cesarean section or pubiotomy seemed the only possibilities. The operation succeeded perfectly and the child was easily delivered with forceps. In spite of a tear of the anterior vaginal wall, no wound complications resulted, but the patient suffered from lameness of the left leg which lasted until the fifth week after delivery and then disappeared completely. While the author is a warm adherent of the operation, he does not believe that the technique has yet been sufficiently perfected to make it a suitable routine procedure for use in private practice.

Congestion Hyperemia in the Treatment of Diseases of the Eyelids.—Hoppe states that he considers Bier's congestion method to be as useful in the treatment of certain affections in the neighborhood of the eye as it has been found in the management of inflammatory conditions in other parts of the body. He first describes experiments made on the healthy eye which have convinced him that the treatment, when properly carried out, cannot in any way injure the eyeball itself, while it is also probable that disorders of the globe can be very little influenced in this way. The most satisfactory results were obtained in cases of hordeolum. The author believes that the hyperemia treatment alone carried out by means of suitable suction glasses at a negative pressure not greatly exceeding 30 mm. of mercury forms the most efficient therapeutic procedure in these cases. Among the advantages are the prompt and permanent relief of pain, the avoidance of troublesome compresses or moist dressings, and the fact that the patients are enabled to continue at work. Furuncles of the eyebrow also yielded readily to this method, but the results in the treatment of chalazion were somewhat less satisfactory, and the author advises that incision be resorted to if prompt improvement does not follow the suction treatment.

Deutsche medizinische Wochenschrift, October 4, 1906.

A Case of Pruritus of the Vulva Cured with Blue Light.—Rothschuh says that in self-defense physicians ought to keep in their own hands and out of those of the quacks such therapeutic agencies as the various forms of light rays. Even although the rationale of their action may not in all instances be evident, striking results are often obtained by the application of some form of phototherapy. He instances a case of pruritus of the vulva occurring in a middle-aged woman which had resisted all other forms of treatment tried, and which, through the insomnia and mental distress occasioned, had brought the patient into a truly pitiable condition. The application of the blue electric light brought relief after the fourth daily application, so that the patient for the first time in a long period was able to sleep several hours consecutively at night. After the twelfth radiation she was entirely relieved and had regained her usual health.

Diaphragmatic Eventration.—Lotze says that although about five hundred cases of diaphragmatic hernia are on record, only twelve cases of the condition named in the title, which consists in an abnormally high position of the diaphragm, have been reported. To this number he adds the case of a man twenty-eight years old who came under observation owing to well-marked diabetes. On physical examination the borders of the right lung were found to be practically normal, but on the left side the diaphragm was at the level of the third rib. Radioscopic examination with a mercury bougie introduced into the stomach showed that the diaphragm was situated above the shadow of the instrument, thus proving that the condition was not one of diaphragmatic hernia. At the end of inspiration the shadow of the bougie was seen at the level of the fourth rib, and at the end of expiration it rose to the level of the second rib.

French and Italian Journals.

Horizontal Succussion in Pyopneumothorax.—Chauffard had under his care three patients, two of whom had pyopneumothorax, and one hydropneumothorax. All attempts to elicit succussion sounds with the patient in the sitting position failed, although in all three of them the effusion was abundant. In order to call forth this phenomenon, the patients were laid flat, face downward. The ear was then applied to the back of the patient and the sound was loud enough to be heard at some little distance by the assistants. With the trunk in an appropriate position, if ventral and dorsal auscultation be successively practised, one may convince himself that the ear hears the succussion sound only when it is applied at the level of the gaseous layer, while it detects nothing at the level of the liquid layer. Succussion sounds are produced when there exists above a free layer of liquid, an air chamber large enough to permit the balottement of the liquid and the resonance of the bruit. Chauffard calls attention to the two kinds of succussion, vertical and horizontal. The former is the classical type and is met with the more frequently. However, its absence does not exclude the possibility of a pyopneumothorax. Horizontal succussion is the proceeding of choice in pyopneumothorax with a large liquid effusion, and in some cases it is the only method that establishes the diagnosis. In every doubtful case succussion practiced on the patient in both standing and sitting posture should be compared.—*Revue Française de Médecine et de Chirurgie*, September 10, 1906.

Intubation of the Nasal Passages in Severe Coryza of Infants.—Minerbi and Vaccari call our attention to the severe obstacle formed by coryza in the nursing infant to lactation. In the Maternity Hospital at Ferrara they have made use of a simple apparatus to permit of breathing while nursing. It consists of a pair of tubes inserted into the nostrils and held in place by a rubber bandage while in use. It permits of breathing, lactation, and sleep, which would otherwise be impossible. Its use is not attended with danger or difficulty. The elastic band is 15 millimeters wide, and passes around to the back of the neck. It is perforated in front with two holes, into which are inserted two Nelaton's sounds, number 11 or 12, which pass into the nares. The sounds should be 65 centimeters long. The apparatus is sterilized by boiling and then introduced into the nares before nursing. Children thus treated nurse and sleep well.—*La Riforma Medica*, August 11, 1906.

A Case of Cardiac Rupture.—Casassus cites the history of this patient. He was a man seventy-one years old, who came to the hospital for a generalized eczema. He appeared to be robust in spite of his age. Both his family and personal history were good. He was taking a nap half an hour after his midday meal, when he was suddenly awakened by extreme pain in the region of his heart. There was vomiting, the face was pale and wore an agitated expression, the forehead was covered with sweat, and the extremities were cold. Slight dyspnea was present. The pulse was small and irregular, being sometimes intermittent. The heart sounds were completely muffled and there was a certain degree of arhythmia. At the end of eleven hours the patient died. Autopsy revealed a rupture of the cardiac muscle on the anterior surface of the organ. This tear was one and one-half centimeters long. Death had been caused by this rupture, followed by an effusion of blood into the pericardium.—*Journal de Médecine de Bordeaux*, September 9, 1906.

Stenosis of the Upper Respiratory Passages Secondary to Tracheotomy or Intubation.—Carlo Comba treats of the mechanical causes of stenosis. The severity of the diphtheritic process may cause ulceration and cicatricial contraction, or there may be a chronic infiltration of the hypoglottic region. Exuberant granulation of the tracheotomy wound at one of the angles, or of the mucous membrane about the tube, is a frequent cause of stenosis. This may result from severity of the disease or mixed infection. Cricotracheotomy is a frequent cause. When the granulations are absorbed results are good. When they are not, cicatricial contraction results. Prophylactic treatment is of importance. Do the high operation, and avoid the cricoid; use well-shaped tubes, not too large, and remove them as soon as possible. Granulations should be scraped and cauterized, and gradual dilatation resorted to when stenosis has occurred. In intubation, aside from a severe or a mixed infection, the principal cause is decubitus. The remedies are the use of light, well-formed tubes, for a short time and introduced skillfully. Pain, bloody sputum, repeated expulsion of the tube, and black spots or concretions on the tube all indicate ulcerations. Some authors advise a secondary tracheotomy after a few days when stenosis persists after intubation. Others cover the tube with a film of gelatine impregnated with alum or iodoform, with good results. If slow dilatation with sounds does not cure the stenosis, divulsion with forceps may give good results. —*Rivista di Clinica Pediatrica*, August, 1906.

Pregnancy in Uterus Didelphus.—Giuseppe Merlo describes a rare case of uterus didelphus in which there was but one hymen, a rare malformation. The patient suffered from severe pain during the early part of pregnancy, probably due to the stretching of the small left uterus, in which the pregnancy existed. The right uterus was empty and menstruation occurred, probably from this side, during the first months of pregnancy. The pregnant side of the uterus was not recognized until after the tumor to the left of the uterus had grown so large as to suggest the necessity of laparotomy for tubal pregnancy. A very careful examination then brought to light a second vaginal orifice, concealed by the hymen. Pregnancy went on to term, a result which is rare in these cases, abortion or premature labor being the usual ending, and the child was born with assistance after a slow labor with rigid os, the knee presenting. There was a perineal laceration and a separation of the lower part of the septum between the two vaginas. The vagina of uterus didelphus may be single or double, or one vagina may be closed. The cause of this anomaly is an arrest of development from the eighth to the twelfth week of intrauterine life, before the formation of the genital cord by the union of the two ducts of Müller. With a rapid increase in the transverse diameter of the embryonal cavity there takes place a slow development of the urogenital folds.—*Annali di Ostetricia e Ginecologia*, June, 1906.

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery, by Representative Surgeons of the United States and Canada. Editors: Joseph Decatur Bryant, M.D., and Albert H. Buck, M.D., of New York City. Complete in Eight Volumes. Profusely Illustrated. Volume One. New York: William Wood and Company, 1906.

It is a curious fact that, while there is no dearth of treatises, large and small, single volumes and systems, on general medicine, gynecology, obstetrics, and pediatrics, modern works on general surgery in the English language can almost be counted on the fingers of one hand. Why this is so it is difficult to say. Surgeons there are aplenty, and good writers there are among them: the journals are filled with instructive articles, and monographs on special subjects are not rare; but of late few surgeons have attempted the writing of general treatises covering the whole field of surgical practice. This is possibly because surgery is in a way more specialized than internal medicine. Practitioners in this branch are prone to interest themselves in a special subject, and the man who has devoted his time to the study of one part or one system, as the gastroenteric or the urinary tract, and has become in a measure identified with work along that line, has a certain hesitancy in setting himself up as an authority on other subjects, with which he feels himself to be less intimately familiar. This, we think, may account for the comparative scarcity of one-man treatises on surgery, and at the same time justifies the preparation of a system of surgery, like the one the first volume of which lies on our table, written by specialists under the direction of competent editors. The prospectus of this work contains the names of ninety-six contributors, each of whom is more or less a specialist in the sense above indicated, and may be presumed to write with authority on the subject assigned to him by the editors. These latter need no introduction to the medical public. Dr. Bryant, himself the author of one of the few extant general treatises on surgery, and the president-elect of the American Medical Association is peculiarly fitted for the task of selection of writers for such a treatise; and Dr. Buck's work in the supervision of the translation of Ziemssen's Cyclopedia and in the preparation of the two editions of the incomparable "Reference Handbook" has placed him far and away at the head of medical editors in this country. With two such able conductors, it would be strange if this work did not prove to be without a compeer in its department of medical literature. But this is prophesy, and we are concerned in the present review with only the first volume of the series.

We are glad the editors or the publishers, or whosever province it was to select a title for the work, did not call it a "manual" of surgery, for manual it is not. This volume is of royal octavo size, next door to a quarto, and has 818 pages; it weighs several pounds, and can be used with comfort only when it rests on the desk. But this drawback, which is due to the weight of the paper necessary in order to bring out the delicate cuts, is forgiven when one contemplates the beauty of the illustrations, in which every line stands out with almost the distinctness of a steel engraving. There are fifteen contributors to this volume, in which only general subjects are treated. Space forbids a detailed review of each article, but we cannot forbear special mention of the introductory article, on the "Evolution of American Surgery," from the pen of Dr. Stephen Smith. No American can read these sixty-seven pages of the surgical history of his country without rising a few inches in stature. There is no spread-eagleism in it, but a simple narration of what American surgeons, many of them humble country practitioners in our Southland, have done to raise surgery from a mutilating makeshift of last resort to a life-saving art of preeminent rank. Abdominal surgery was born here, and anesthesia, which made progress possible, was, as we sometimes forget, an American discovery; so was the cause of puerperal fever, a truly traumatic, hence surgical, disease. Dr. Smith's article is illustrated with the portraits of many of the surgical worthies of the early and more recent times, the features of some of whom are familiar to many still living, and will recall to them affectionate memories of the masters under whom they studied. Following this introduction are sections on "Surgical Pathology," by Drs. Aldred Scott Warthin of Ann Arbor, Albert George Nicholls of Montreal, Edward H. Nichols of Boston, Theodore A. McGraw of Detroit, and Harvey R. Gaylord of Buffalo; "Complications and Sequelæ," by Drs. Paul Monroe Pilcher of New York and Joseph C. Bloodgood of Baltimore; "General Surgical Diagnosis," by Drs. Joseph D. Bryant of New York, Harlow Brooks of New York, Preston M. Hickey of Detroit, Walter J. Dodd and Robert B. Osgood of Boston; "General Surgical Treatment," by Drs. James E. Moore of Minneapolis; and "General Surgical Prognosis," by Dr. Leonard Woolsey Bacon of New Haven, Conn. Each of the articles in these five sections is worthy of a special review, but the limits of a book notice forbid, and we can only say that were each published as a monograph it would bring to the author the commendation of his confrères in general practice. If the succeeding volumes reach the high level of this introductory one, the work will take rank as one of the greatest surgical treatises any country has yet produced.

A Complete Handbook for the Hospital Corps of the U. S. Army and Navy and State Military Forces. By Charles Field Mason, Major and Surgeon, U. S. Army. Approved by the Surgeon-General of the Army and Navy. Profusely Illustrated. New York: William Wood and Company, 1906.

This work is intended to supply all the information needed by enlisted men of the Hospital Corps in the army, navy, and militia, in their professional and military duties. It replaces and combines several separate small manuals, each of which contains too much. In addition to some very elementary instruction in anatomy, physiology, nursing, and first aid, it contains chapters on cooking for the sick and management of the ration, hygiene, camp sanitation, army regulations, care of animals, riding, driving, litter drills, transportation of the sick, and the Geneva convention—a comprehensive list of subjects which shows the wide range of studies and training demanded of the modern sanitary soldier. A case is known in which a hospital sergeant, despairing of learning all these things, refused to apply for examination for promotion, but took in preference the examination for a commission and was appointed a second lieutenant of cavalry. The present work must indeed appear encyclopedic to the ordinary soldier, and it suggests the thought that perhaps too much is expected of men who are paid so little—if it is easier for a man of moderate education to become an officer. None except sergeants are expected to know all of this hand-book, and it seems that there is need of an abridged edition, which is wholly within the comprehension of every private soldier who is not a student but who can be compelled to learn all of it in his three years of service. Nevertheless the work fills a long-felt want of medical officers in supervising the everlasting grinding instruction of their enlisted men, who invariably specialize as in civil life and are generally kept at one line of work, such as cooking, clerking, nursing, or muledriving.

Natality and Fecundity. A Contribution to National Demography. By C. J. Lewis, D.Sc. (Public Health), M.D. Edin., F.R.C.P. Edin., M.R.S.C. Eng.; Lecturer on Public Health, School of Medicine of the Royal College and Medical College for Women, Edinburgh; Examiner in Public Health, Royal College of Physicians Edinburgh; Fellow of the Royal Institute of Public Health; Joint Author of "Public Health and Preventive Medicine," and J. Norman Lewis, Fellow of the Institute of Actuaries; Fellow of the Faculties of Actuaries in Scotland. New York: William Wood and Company, 1906.

The authors have made a remarkable study of the birth registers of Scotland for 1855—the year in which compresensive details were recorded as to both child and parents, such as birthplaces, ages, time of marriage, and number of children; no other vital statistics of this variety are so complete, and there have been numerous requests to have them properly tabulated—a stupendous work which the Lewises have successfully accomplished. Fertility refers to the number of children born and fecundity to the number of successful pregnancies, irrespective of multiple births. These matters have been worked out for each five-year age period of mothers from fifteen to fifty-nine, and of fathers to a more advanced age. Multiple births are accurately determined, twins, for instance, occurring once in 87 births and triplets once in 8,391. The reduction of the birthrate since 1855 comes up for discussion statistically, but it is not explained. A gratifying exhibit is the marked reduction in the illegitimate births since 1855, but it is not known whether it is a result of greater morality in Scotland or of more knowledge. The statistics are of great value, for they give an accuracy to general laws known for a long time, though happily they do not change any of our previous generalizations on these topics.

The Teeth and Their Care. By Thaddeus P. Hyatt, D.D.S., Member Second District Dental Society of the State of New York. Brooklyn-New York: King Press, 1906.

This small handbook is full of practical suggestions. The structure of the teeth, their care, children's teeth, and the relation of the teeth to the rest of the body are treated of in different chapters.

Society Reports.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

Second Annual Meeting, Held at Washington, May 17 and 18, 1906.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 318.)

SOCIOLOGICAL SECTION.

Thursday, May 17.

DR. WILLIAM H. BALDWIN OF WASHINGTON IN THE CHAIR.

Tuberculosis Nostrums.—Mr. SAMUEL HOPKINS ADAMS of New York read this paper. He spoke of the great array of patent medicine advertisements to be seen everywhere, which gave one the impression that anyone could cure tuberculosis except the regular medical practitioner. He divided these so-called remedies into the actively harmful, including those which contained such drugs as hashish, opium, and alcohol, and the passively harmful, which simply stimulated false hope and diverted the patient from the use of proper remedies. He believed, however, that this vicious business was now on the wane. As one of these quacks had told him "the public is getting wise on consumption," and it would be necessary for him to turn his attention to some easier disease, as cancer. There could be no doubt that the work of the National Association for the Study and Prevention of Tuberculosis, as well as the work being done in the public schools, was arousing the public to a proper consideration of the subject. He desired to urge every speaker to devote a few words to explaining the uselessness and harmfulness of so-called consumption cures. He referred to the attempts to pass bills for the restriction of the patent medicine business, and explained in detail the difficulties that had been encountered in various States. He said that many of the better newspapers had now taken up the fight and were excluding such advertisements from their columns.

Dr. FRANK BILLINGS of Chicago opened the discussion on this subject. He said that formerly we did not understand what tuberculosis was, and its only management was by the use of drugs, which were of several kinds; first, preparations intended to improve the nutritional condition, as the fats, cod liver oil, and other hydrocarbons; second, preparations supposed to modify to some degree the changes occurring in the tubercle, as the phosphates, calcium phosphate, for instance, with the idea of bringing about calcareous degeneration of the tubercle. Then we had the remedies to combat fever, as aconite and other preparations of that kind. Lay people believed to-day what was taught and believed by the medical profession fifty years ago. It was unfortunate that a large number of the medical profession itself was no better educated in this matter than the laity.

Dr. J. WILLOUGHBY IRWIN of Philadelphia said that he had had occasion to interview a great many druggists on the question, and had been informed that it was almost always the poor who bought the nostrums, because they could not afford to pay the ordinary fee to a physician and then go to the store and pay another fee for the medicine. They tried to even this up by buying something that they supposed would at least do them no harm and would help their cough, their chief idea always being to get rid of the cough, which they looked upon as the disease itself. He thought a committee should be appointed by the association to take charge of the crusade against the nostrums advertised for the cure of consumption. He suggested as one method that the committee should write to druggists asking for the names of five or more people using such remedies and mail them literature. This would be taking up the matter in the manner that the patent medicine men themselves used.

Dr. D. S. WILSON of Louisville, Ky., said he could not refrain from saying a word in defense of the druggist. He believed that as a general rule they did not desire to sell patent medicines, first, because there was little profit in it for themselves, and, second, because as a class they were as conscientious as physicians; but the trouble was that the people demanded the nostrums and that, as the drug business was a trade as well as a profession, they could hardly be expected to refuse to supply the demand.

Tuberculosis Among the Indians.—Commissioner FRANCIS E. LEUPP of Washington, D. C., presented this paper. He said, as the safe guardian of 270,000 red children, he felt the keenest interest in the investigation of the cause and the search for preventive and remedial measures to be used in combating this special scourge of the Indians, tuberculosis. During the last year they had collected at the office of Indian Affairs data from ninety-one of their field physicians, representing the conditions among half the Indian population of the United States. These reports showed that among every 1,000 Indians there were nearly ten cases of pulmonary tuberculosis, fifteen of glandular tuberculosis, and nearly two of tuberculosis of the bones and joints. He also gave statistics from the larger Indian schools. At Carlisle, where, in the judgment of so many Western persons, Indians readily sickened and died, there were ten cases of tuberculosis in a total membership of 904. On the other hand, at Pierre, S. D., in the midst of a country where it was customary to send white persons with weak lungs, there were eleven cases out of a total of 146. At Chilocco, Oklahoma, one case among 748 pupils. At Haskell, Lawrence, Kansas, one case among 814. He referred to the recommendation made in his annual report for 1905 as to the necessity of the separation of diseased from well children. He had also appealed for authority to distribute circulars regarding the prevention and spread of the disease.

Dr. JAMES R. WALKER of Pine Ridge, S. D., read a paper upon the same subject. In 1878 he had gone among the Indians to die of tuberculosis, bidding his friends goodbye and never expecting to return among them. When he got among the Indians he thought it might be well to make some study of the material at his command, and in time he had come to see things that were not written in textbooks. It was of his work among the Sioux that he spoke particularly. He had found the Indians affected with the disease to a much greater degree than the white residents. The population of Pine Ridge was 6,686; 4,870 full-blooded Sioux and 1,816 mixed bloods. For ten years an effort had been made to keep statistics, and the data so obtained formed the basis of the paper. He found that tuberculosis among the Indians did not differ in any respect from the disease among the whites; it ran the same course and produced the same results. When they abandoned the tepee and began to live in houses the disease greatly increased. He considered that the question of food was only a question of fortifying the system against disease, and said there was no evidence that meat, even though tuberculous, caused the disease among these Indians. The sanitary condition of the tepees had been far superior to their houses, which had been built in the most unsanitary manner. The conditions were such as to lower the resisting power of the Indians rapidly. Every case was caused by the excretions of the disease, and no case developed in any other way. It had been fully demonstrated that tuberculosis could be prevented among them by keeping them from exposure to the infection. He submitted the proposition that a practical method of suppressing tuberculosis among the Indians would be to establish sanitary camps, where all the infected should be collected and maintained until each case terminated.

Mr. M. K. SNIFFIN of Philadelphia had been at Pine Ridge during the summer and had had an opportunity to investigate the conditions there, which were such that it was not surprising that the death rate from tuberculosis

was so high; it was more surprising that it was not a great deal higher. He said the territory under Dr. Walker's charge was about the size of the State of Connecticut, with a population of about 7,000, and the only way to get to them was by means of horse and wagon; it often required a week's time to reach a patient. Another of his difficulties was that after prescribing it was almost impossible to have his instructions carried out. He thought too little attention had been paid in the past to the medical service of the Indian Department, and that it should be thoroughly remodeled. He thought the force should be increased, as it was out of the question to expect one or two physicians to look after the health of 7,000 of these people. The conditions in the Indian homes were most unsanitary, often as many as fifteen occupying one hut, to say nothing of as many dogs. If the Indian was to be built up, decent permanent homes must be established for him, and he thought the association could do much in bringing public sentiment to bear upon Congress to furnish proper means to carry out such measures.

Dr. Norman Bridge of Los Angeles said the papers had demonstrated his own belief that tuberculosis spreads because of lack of fresh air and proper hygienic surroundings as well as by the distribution of the germs of the disease, by lowering the resisting power of the individual. He desired to know whether it had been Dr. Walker's experience, as had been stated by some, that the existence of tuberculous glands of the neck lessened the likelihood of the individual acquiring pulmonary tuberculosis later in life. He had found that among people with scrofulous scars the proportion of pulmonary tuberculosis was about one-half.

Dr. Walker said, in answer to Dr. Bridge, that he had no statistics on the subject, but he had certainly seen many cases of pulmonary tuberculosis in patients who had had tuberculous glands earlier in life.

Dr. Geo. M. Kober of Washington, D. C., said his sympathies were very much with the Indians, among whom he had lived in the capacity of military surgeon for eighteen years, and he thought Dr. Walker had struck the keynote of the whole situation in placing as the most effective predisposing cause of tuberculosis among the Indians the radical change in their mode of living. We had taken the Indian from his tepee without suggesting to him how he might build a sanitary home, so that from the well-ventilated tepee he had gone into a hut of the most unsanitary construction. Proper food and proper housing would do more than anything else to solve the problem for the Indian, and he thought that the attention of the Commissioner of Indian Affairs should be called to Dr. Walker's excellent paper.

Tuberculosis Among the Negroes.—Dr. Thomas Jesse Jones of Hampton, Va., read this paper, in which he aimed to show the great importance of the study and prevention of the disease among this race. He believed that few knew the extent of the prevalence of the disease in this race, and that still fewer knew of its effect upon the vitality of the nation. There were three factors that had to be considered—the extent of the disease in the race, the proportion of that race, and their proximity to other races. He demonstrated the great prevalence of the disease among the negroes of the South and considered that it was such as to demand the most careful consideration of the association. He thought that in this respect only the Irish offered a problem at all comparable with that of the colored race. He said we could not afford to overlook the reflex of the black race upon the white, and unless the white race could lift them up, he believed they would surely pull the white race down

Dr. Robert Wilson of Charleston, S. C., said that he thought those living in Northern cities, where the proportion of blacks to whites was so much less than in the South, could scarcely appreciate the importance of Dr. Jones' paper. He agreed with Dr. Jones that it constituted a menace to thousands of the white population, because the two races were brought into contact in every relation of life. Dr. Wilson gave a series of statistics bearing upon the question dating back from 1822. The great prevalence of the disease in the negro race he believed was due to two factors, ignorance and poverty. They were too poor to live in proper quarters and too ignorant to take care of themselves. He suggested as a means of remedying the condition sanitary inspection of their quarters and segregation as a help toward this end.

Dr. S. A. Knopf of New York said that among other things we must endeavor to educate the negro physicians who did not seem to have grasped the importance of the subject at all. He thought that much of the trouble in the negro race in the cities was due to their long hours of work and their irregular habits of living. They had to be taught that proper and regular methods of living were the only things that would remedy the condition. He considered the problem a most serious one and that it was essentially necessary to combat the disease in this race in order to keep it from the white race.

Dr. C. L. Minor of Asheville, N. C., said that the statistics concerning tuberculosis among the negroes in the South were absolutely worthless, not worth the paper they were written on. In his experience no negro who developed the disease ever recovered. Unless the disease could be prevented nothing could be done. He believed that the disease would eventually settle the whole race question. Any preventive work would depend upon the intelligence of the negro, and unless that could be raised little could be accomplished.

Friday, May 18.

Workingmen's Insurance as an Instrument of Tuberculosis Prevention.—Dr. Arnold C. Klebs of Chicago read this paper. He said the money which set into motion and kept working the ever-growing machinery of tuberculosis-prevention in this country was, with few exceptions, supplied by voluntary contributions given with charitable intent, this holding good for almost all our public hospital and relief service; as Duclaux expressed it, "we have remained anchored to that idea of charity, a very noble, very beautiful idea, looked at from the view point of one who follows it, but a false, almost absurd idea, when one contemplates the benefits society can possibly derive from it." If the right and duty of self-defense, he said, was to be the basis of our efforts, then it was the one most attacked who should bear the largest share of the burden; to make him who was attacked, though he had not succumbed yet, an object of charity was demoralizing and pauperizing. It was the working man, especially the one employed in industrial enterprises, without doubt, who was the most often attacked, and it was he who must grapple with the problem. He then referred to the system of obligatory insurance for workingmen in Germany, and said it had become the most powerful factor in tuberculosis prevention in that country. Every working man of a certain age scale was obliged by law to insure himself and his family against sickness, invalidism, and old age. The employer deducted one-half of a certain proportion of the wage and after adding the other half himself remitted the total to the insurance authorities in charge of the fund. The contributions were a trifling tax to the workingman, but the benefits were great. Under the law for sickness insurance there had been paid for the benefit of the insured from 1885 to 1903 three hundred million dollars, and from the invalidity insurance from 1891 to 1903 two hundred million dollars; during the past eight years the invalidity insurance offices took care (for an average of three months for each case) of 101,806 tuberculous patients at a total expenditure of about nine million marks; 90,000 of these patients had been taken care of in sanatoria established by the insurance offices. He thought the necessity for individual submission to social exigencies was becoming more and more appreciated in this country, and in this tuberculosis must become the most important point of attack. The industrial

workers had a tremendous interest in this struggle and it was necessary to show them how to help themselves, how to save in time a penny to be ready to meet this greatest of their foes.

Mr. Frederick L. Hoffman of Newark, N. J., discussing Dr. Klebs' paper, said that it must be borne in mind that there was a wide difference between a paternal government and a republic, and that anything in the nature of paternalism would be distasteful to people in this country. He considered the method in Germany was really a charity and not an insurance, and to attempt such a thing in this country would bring about a social revolution. Society had an important duty and that was to teach how the disease could be prevented, and how it could be cured, and the trouble here was that the workingman did not realize that he had nine-tenths of the problem in his own hands. He believed that the only solution of the matter in a democracy was so to develop the intelligence and brain power of every man that he would be able to solve the problem for himself. He did not believe the German method was anything but a charity under a different name.

Mr. Wm. H. Baldwin of Washington said he thought the chief benefit of the German insurance was that they had realized that tuberculosis was a terrible drain and had found a method of curbing it by getting at the disease as rapidly as possible and having the prevention and cure go on together.

Dr. J. H. Lowman of Cleveland, O., disagreed with Mr. Hoffman that the workingman must be left to solve the problem for himself; it could not be done that way; society must help him; it was for such associations as this to point the way. This had been attempted in a way in the inspection of shops which met with favor both from the workingman and the employer.

Dr. Klebs, in closing the discussion, said it was a fallacy to believe that the prevention of the disease lay in the workshop; it did not; it lay in the family, in the home, not in the factory, and he believed it could not be reached there with anything as well as with such insurance.

The Influence of Sanatoria on Surrounding Property.—Dr. William H. Baldwin, Washington, Chairman of the Section, delivered an address on this subject. Mr. Homer Folks of New York, Dr. John P. C. Foster of New Haven, Dr. H. Wirt Steele of Baltimore, and Mr. Livingston Farrand of New York discussed the subject, giving their experiences and the difficulties met with in securing sanatoria in their respective localities.

Effective Methods of Educating the Public.—Mr. Paul Kennaday of New York read a paper on this subject, in which he described the various methods that had been employed in reaching the public, dividing the educational work into three classes: 1st, lectures; 2d, publications; and 3d, exhibitions.

Surgeon General Wyman, P. H. and M. H. Service, spoke particularly on the prevention of tuberculosis in Government Departments, and of the Executive Order issued February 28, 1906, containing the necessary directions towards this end. The Executive Order of President Roosevelt was issued in pamphlet form, entitled "Prevention of Tuberculosis Among Government Employees." The order referred to persons and to buildings and prescribed rules to be followed, the nonobservance of which would constitute a cause for separation from the service.

Dr. John H. Lowman of Cleveland, Dr. Edwin D. Solenberg of Minneapolis, Mr. Alexander M. Wilson of Boston, Dr. Rogers of Yonkers, N. Y., Mr. Samuel H. Adams of New York, Dr. D. S. Wilson of Louisville, Dr. W. Wirt Steele of Baltimore, and Health Commissioner Darlington of New York, discussed the subject, showing in detail the various methods employed by them in their respective localities for bringing before the people exhibitions, lectures, and demonstrations, and distributing publications intended to arouse public interest in the work of tuberculosis prevention.

SECTION ON TUBERCULOSIS IN CHILDREN.

Friday, May 18.

Dr. Wm. P. Northrup of New York in the Chair.

Address of the Chairman.—Dr. William P. Northrup of New York said there had been a request for a Section which would devote itself to the study of tuberculosis in children and this request had called forth a ready response from the President. Tuberculosis in young children had a few characteristics peculiar to the age of the patients. It was less apt to be limited to the lungs and to manifest itself in excavations with profuse expectoration. Tuberculosis in infants and young children was more apt to be of general distribution, or to be localized in lymph nodes, bones, lungs, and meninges. The program took account of the sources from which the infectious agent was most commonly derived, its hiding places, the portals through which it gained entrance to the body tissue, the protection of infants in menacing surroundings, the effort to limit the progress of the disease, and the hygienic aids of greatest value in assisting the body cells against the germ cells. There was no better place to begin the study and prevention of tuberculosis than in young children.

The Portals of Entry of Tuberculosis.—Dr. David Bovaird, Jr., of New York said that the very fact that discussion of the subject was still appropriate bore eloquent witness to the truth of the ancient aphorism of Hippocrates, that "experience is fallacious and judgment difficult." From the days when the experiments of Villemin proved the transmissibility of tuberculosis it had been accepted that the inoculation of tuberculosis would result in a definite succession of events in the affected animal. There would be a local lesion of the cellular tissues or skin in cases of subcutaneous infection, of the peritoneum if the material were injected into the sac, of the intestines in cases of feeding experiments, of the lungs when infected dust was inhaled. Then the lymphatic glands nearest the original focus would become diseased, one gland after another, until the deep thoracic or abdominal glands gave away and the disease invaded the viscera or the bacilli were transmitted everywhere throughout the body by the blood. Within a few years doubt had been thrown upon this belief. Some feeding experiments had not resulted in abdominal but in pulmonary tuberculosis. In some cases the local lesion of skin or intestine was found lacking. After reviewing the conclusions of Cornet on this theme Dr. Bovaird said that the older methods of interpretation of the findings in tuberculosis in man were reestablished as entirely trustworthy. With that understanding there were five different routes by which tubercle bacilli might obtain entrance to the body: (1) By placental circulation; (2) by contact with the surface of the body, the skin, the eye, the ear, etc.; (3) by the respiratory tract; (4) by the digestive tract; (5) by the genitourinary tract. Infection through the placenta was possible, but so rare that it might be disregarded for the present. Infection through the genitourinary system was practically unknown in childhood. When it occurred it was a part of a general infection. Infection through the skin was also of minor importance. It had long been assumed that some wound or lesion of the skin or surface was essential to the lodgement of the tubercle bacillus. Cornet had demonstrated that the bacillus might make its way through the uninjured integument, but this source of infection played an insignificant part. Surface lesions usually remained local. The two great portals of entry were by the respiratory and digestive tracts. The relative importance of these two avenues of infection was best understood by discussing their relations to the more important clinical types of tuberculosis in children. Glandular tuberculosis might be produced by either inhalation or ingestion of the bacilli—probably most often by inhalation. Tuberculosis of the bronchial lymph nodes or lungs was an inhalation tuberculosis. Tuberculosis of the meninges or bones and joints in the great

majority of cases (9-10) had its primary focus in the bronchial nodes or lungs. Tuberculosis of the alimentary tract was primary in a very small percentage of cases. With reference to the sources of the bacilli which might infect children he said the unity of tuberculosis in man and animals was established beyond question, so discussion was reduced to the query as to whether the tuberculosis of children was derived *in toto* from previous cases in man or in part produced by tubercle bacilli present in the milk of diseased cows. The author was convinced that the part played by the bovine disease was a minor and for the present unimportant one. His reasons were the rarity of primary intestinal tuberculosis in children in this country, though there were many more cases of this kind in England and Scotland. Again the paucity of cases in which the development of tuberculosis in children could be reasonably referred to the ingestion of the milk of tuberculous cattle. Five years ago he was able to find scarcely a score of such cases in literature and in the meantime he had failed to add materially to that number. The most conclusive argument against the influence of milk as an agent in the communication of tuberculosis to man was to be found in the studies of Biedert and Ganghofner, who made careful comparisons between the number of tuberculous cattle and the number of deaths from tuberculosis in man in several districts of the country. They could discover no relation between the factors and concluded that while bovine tuberculosis was transmissible to man, such transmission played no part of importance in the prevalence of tuberculosis in man, and more particularly in children. The source of the bacilli which conveyed tuberculosis to children was therefore to be sought in other cases of human tuberculosis. The danger lay more particularly in the expectoration of consumptive patients. Control or conquer that source of infection and tuberculosis among children would sink into comparative insignificance.

Protection of Infants and Young Children from Tuberculosis Infection.—Dr. John Lovett Morse of Boston read this paper.

Arrest (Cure) of Tuberculous Processes in Infants and Young Children; Fresh Air; Seaside Hospitals.—Dr. John W. Brannan of New York read this paper which described in detail what had been accomplished at Sea Breeze, Coney Island, especially in the case of children with tuberculosis of the bones and joints.

Dr. Wm. P. Northrup of New York said that the Sea Breeze Hospital was next to Luna Park, Coney Island, and that many people could be seen hanging around there watching the patients play and romp, and not one of them but had a game leg. Dr. Wallace certainly had an awful collection of the ragged end of humanity, but he loved them and they all did well.

Dr. George M. Kober of Washington said that he wished to go on record as a believer in the transmission of bovine tuberculosis through the medium of the milk supply. According to Dr. Salmon it had been proven that in some countries from 40 per cent. to 50 per cent. of the cows had tuberculosis; in the United States the proportion was not so great, being probably not over 5 per cent. in the worse affected states. Theobald Smith, in 1893, from a number of experimental observations found that the tubercle bacilli might be present in the milk, when the udder so far as the naked eye could determine contained no foci of disease. The general results of inoculation experiments would seem to indicate that the infectious properties were greater with milk from animals with udder lesions and next from those affected with general tuberculosis. In 1903 Dr. Kober published 86 cases of milk bovine tuberculosis and offered the following conclusions: 1. Tuberculosis may be transmitted to man in milk from tuberculous cows; the danger from this source was real and could not be measured by the actual number of recorded cases, but should be judged in part at least by the inoculation and feeding experiments and the accidental wound infections which had established the intercommunibility of bovine and human tuberculosis. 2. The degree of danger might also be estimated by the prevalence of bovine tuberculosis and of the forms other than phthisis pulmonalis in man, remembering that the infectious qualities of milk were greater when the udder was the seat of lesions, and that Gebhardt's experiments had shown that tuberculous milk when diluted with the milk of sound animals in the proportion of 1 to 40 lost its infective power. 3. Further research seemed desirable with a view of determining the frequency of primary intestinal and abdominal tuberculosis in all cases which come to autopsy whether the child perished from tuberculosis or not, and in these autopsies the bacteriological examination should be directed to the existence of the two types of tubercle bacilli originally referred to by Smith, and whether the bovine type predominated in the so-called scrofulous lesions.

Dr. Norman Bridge of Los Angeles, Cal., said that it should be a matter for congratulation that Dr. Bovaird considered that there was so little danger of infection of children by milk in this country. He would not argue, however, that we should be less careful of the milk supply. The various cities in this country are coming, one after the other, to adopt a system of inspection of dairies. We were not justified in saying that human tuberculosis could not be produced by bovine bacilli.

Dr. Mazyck P. Ravenel of Philadelphia said that those people who believed that milk was not a means of infection in tuberculosis were those who might say that there was no relation between the tubercle bacillus and the disease. Children were infected with the bovine germ. A gentleman in England has made the statement that in 30 per cent. of the children with tuberculosis there was found the bovine bacillus. The human bacillus was the chief danger to mankind. But after the bovine bacillus had been a resident of the body for a certain period of time it could not be differentiated from the human bacillus; therefore, in a large proportion of the cases one could not say whether the infection was from the human or the bovine bacillus.

Dr. Bovaird agreed that infection by the bovine bacillus had been proven beyond a doubt, but what he had tried to point out in his paper was its infrequency. Dr. Ravenel had stated that in England 30 per cent. of the cases examined showed a distinct type of bacilli of the bovine variety. The point of special interest lay in the primary focus, particularly as the disease occurred in children, with tuberculous disease of the bones and joints. These latter were not the original foci. In most cases one would find unmistakable evidence of the disease in the respiratory organs. If this society expected to do much in the way of prevention of tuberculosis, it should first look for the original source of the disease and not to the amount of damage done in the bones and joints. Primary tuberculosis had been demonstrated in the tonsils. Children more often died from pulmonary tuberculosis than from tuberculosis of the bones and joints.

Dr. S. A. Knopf of New York said that he did not fear the air of New York City, but the dust that was contained in it, and he always advised his tuberculous or other patients to hold the hand before the mouth, not to talk in the open, and to breathe through the nose. A point that had not been sufficiently emphasized was that these children should be taught not to fear not only draughts but also the night air; "night air is a night mare." At Sea Breeze there was an absolute fearlessness of pure air and night air.

Dr. Wallace of Sea Breeze, Coney Island, after referring to the great help, moral and financial, that Dr. Brannan had been to them at Sea Breeze, told of the treatment of these children, and spoke under four heads, as follows: (1) Sea air night and day; (2) ample nourishing food; (3) the establishment of a happy, cheerful, and childlike normal disposition; (4) the orthopedic treatment, which

was carried out with but little manipulation, as little as possible.

Resolution.—Dr. JOHN W. BRANNAN of New York offered the following resolution:

Whereas, Recent experience in Europe and in this country has shown that out-door life in pure air has the same curative effect in surgical tuberculosis as in tuberculosis of the lungs; therefore be it

Resolved, That in the opinion of the members of this Section, hospitals and sanatoria should be established outside of cities, either in the country or on the seashore, for the treatment from its incipiency of tuberculosis of the bones, joints, and glands in children.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 8, 1906.

DR. MATTHIAS NICOLL, JR., IN THE CHAIR.

A Case of Aortic Stenosis in a Child Eleven Years Old.—Dr. JOHN HOWLAND presented this patient, a girl, 11 years old, whose heart condition was discovered during a routine examination by a school inspector. The entire interest in this patient centered upon the physical examination. Upon inspection there was noted a heaving impulse on the left side of the chest with the apex beat in the fifth intercostal space, one and one-half inches to the left of the median line. Over a considerable portion of the precordium a thrill could be localized, with its greatest intensity over the second intercostal space on the right side. One murmur was heard at the apex; this was transmitted to the axilla, to the back, and was systolic. A second murmur was heard, harsh, with greatest intensity at the second intercostal space on the right; the sound was transmitted to the vessels of the neck, into the axillary and brachial arteries, being heard about three inches down the left arm. The second pulmonic sound was accentuated. There was a *pulsus tardus.* Aortic stenosis was extremely uncommon at the age of 11 years. Northagel had stated that a congenital stenosis was incompatible with life. The patient presented had a mitral insufficiency as well, and one would hardly say that the mitral lesion was acquired on top of a congenital aortic stenosis.

Lipomatosis Universalis in an Infant Eleven Weeks Old.—Dr. JACOB SOBEL reported this case, with photographs. The child was eleven weeks old. The mother was 24 years old, a first cousin to her husband. She was the mother of three children. The first child appeared normal, and was born at full term. The second child had a normal birth and appeared normal until the fourth week, when enlargement of the head and fat accumulation were noticed. This child subsequently became blind, and died at the age of eight months from bronchopneumonia complicating, or, as a terminal infection of, amaurotic idiocy. The third child, the subject of the report, was born after a normal labor. Nothing unusual was noticed until the fifth week of life, when a fullness of the cheeks was noticed when, warned by her previous experience, the mother sought advice. The fat continued to collect in the nape of the neck, the chest, the suprapubic region, and other parts of the body. Here followed a complete report of the history. In his general remarks Dr. Sobel said here was a child, eleven weeks old, of normal birth, of Hebrew parents, related as first cousins, who at five weeks showed the first signs of illness in the form of fat accumulation in the cheek. Following this there was a general obesity, so that in certain parts, as the abdomen, neck, back, thighs, and buttocks, large masses of fat could be grasped with the hand. Coincidently the child became less sensitive to its surroundings, cried at night, appeared to be blind, had bronchitis, weakened perceptibly, and finally died at the age of three months. During all this time the head was held erect and did not fall backwards. This history, including the partial blindness, corresponded to cases of lipomatosis. But with a similar history in a brother who died of amaurotic idiocy at the age of eight months, and with an absence of ophthalmoscopic examination, it might be questioned whether the case was one of uncomplicated lipomatosis. Generalized obesity was uncommon in amaurotic idiots. The holding of the head erect was presumptive evidence against amaurotic idiocy. In view of this history he recorded the case as one of lipomatosis universalis infantilis, unusual in itself, but more so because of the possibility of its being associated with or complicating amaurotic family idiocy.

A Case of Exophthalmos.—Dr. F. S. MEARA presented a child, seven weeks old, who had a very extensive nevus. There was an anomalous appearance of the ear and a discharge from the umbilicus which had existed since birth. There was a decided exophthalmos of the left eye, and he believed there was a possibility that the child might have some dilatation of the retrobulbar veins, as had occurred in the nevus. There was no history of cerebrospinal meningitis; there was no aneurysmal varix, nor thrill over the affected eye. Dr. Cutler, who examined the child, called attention to an enlargement of the eye. There was the suggestion of a possible congenital glaucoma.

Rachitis in a Child of Eleven Years.—Dr. HERMAN SCHWARZ presented a boy almost 12 years old, who was of normal birth and development. When nine months old he had had prolapse of the rectum and the mother was told that he was rachitic. He had been breast fed until eleven months of age, and afterwards fed on starchy foods. He had been constipated most of his life, and had headaches, dizziness, and vomiting. When seen six months ago by Dr. Schwarz there was nothing abnormal except that his head was typically rachitic and there were more leucocytes than usual in the blood. The tonsils were large and there were adenoids. He had the peculiarly shaped rachitic chest, with beading of the ribs, and protuberant abdomen. The spleen and liver were enlarged. The extremities were deformed, and there was a nodule to be felt at the outer edge of each ulna. There was also a scoliosis and kyphosis. There were 340 grains of urea passed daily and albumin in the urine. It was remarkable that the deformities of rachitis should have been so extensive, and while the rachitic features were progressive, they had been stationary for a number of years. While rachitis was the most likely diagnosis, the condition might be an infantile osteomalacia. Osteogenesis imperfecta was also considered as a possibility, but it was usually believed that this latter affection was fatal at time of birth, or soon after. He thought the case was one of rachitis of persistent form. Phosphorus, cod-liver oil, etc., had been given with but little result.

Dr. NATHAN advised surgical measures if the deformities did not clear up under present treatment. The case showed that disturbances of metabolism might continue beyond childhood and result in bone deformities resembling those of rickets and yet differing from rickets in the absence of certain symptoms which were usual in rickets. In children with osteomalacia the signs were the same as in rickets, as far as the bones were concerned. When the nutrition of the bone was interfered with, certain conditions took place in the bones that simulated rickets, with an irregular formation of uncalcified bone and thickening of the epiphyses due to irritation of the soft bone. In the absence of metabolic deformities in the bone one could not say that the condition was due to malnutrition from improper food.

Dr. Charles Herman said that he had seen a similar case several years ago. Some other disease of the bone besides rickets was probably present. The child did not appear to him to be as intelligent as he should be at that age.

Report of a Case of Hypertrophic Pyloric Stenosis; Operation; Exhibition of Specimen.—Dr. Louis Fischer presented this communication. After a review of the literature on the subject the case was reported, illustrating a typical hypertrophic stenosis of the pylorus in which the active symptoms began when the baby was six weeks old. The child weighed 8½ pounds at birth, was well developed, and nursed vigorously. The child gained in weight and slept four and five hours at a time. When six weeks old he suddenly commenced vomiting after each nursing. There was no gain in weight; the vomiting occurred several hours after feeding. The amount vomited ranged between one and two ounces; sometimes as much as eight ounces. Weaning was ordered and a wet nurse provided, but the vomiting continued as before. After one week the wet nurse was discharged and various home modifications of milk were ordered, but without improvement. Dr. Fischer first saw the child when he was two and one-half months old. Emaciation was extreme, the skin had lost its normal elasticity, and there was a very thin layer of panniculus adiposus. The weight was 7½ pounds, one pound less than at birth. The physical examination showed a stomach which appeared like a distended balloon at times, at others flat. Tympanitic note was obtained on percussion. There was also a splashing sound very distinctly heard when the organ was palpated. Strong peristaltic waves were noted when the baby was fed, extending from left to right. There was a distinct hour-glass contraction, the stomach bulging on either side with a sulcus in the middle. These active peristaltic and antiperistaltic waves were at times so strong that the stomach appeared like a double bulb seen on an ordinary atomizer. These waves were usually followed by vomiting. Although the baby was but ten weeks old, the capacity of the stomach was about fourteen ounces. Not only was the baby suffering from a pyloric stenosis, but also with an acute dilatation of that organ as well. The siphoning of the gastric contents was effected several times, and a marked insufficiency was found. Early in the disease vomiting was occasional, but as the symptoms progressed vomiting became more frequent and followed the ingestion of any liquid. The trained nurse counted twenty-seven large and small vomiting attacks in twenty-four hours. Examination of the gastric contents showed the presence of lactic acid and a total absence of hydrochloric acid. The condition of the bowel was decidedly characteristic. At two and one-half months the child weighed two pounds less than at birth, and the prognosis was bad. Surgical treatment offered the only plausible relief, and operation was decided upon.

Dr. Arnold Sturmdorf said that on January 17 he was requested to perform an immediate operation for the relief of a congenital hypertrophic stenosis of the pylorus in the case reported by Dr. Fischer. At the time of operation the extremely emaciated, atrophic infant presented a weak but distinctly perceptible pulse of about 120. Through an inch and a half incision carried slightly to the right of the midepigastric line, the hypertrophied pylorus was drawn forward, just sufficiently to bring the duodenum and the pyloric end of the greater curvature of the stomach into easy apposition, somewhat in the manner of the first step in the Finney operation. The contiguous parts were rapidly anastomosed by double tier sutures and the abdomen closed. The time consumed in actual operative work was twenty-two minutes; the administration of the narcosis had to be interrupted many times because of the condition of the child; this, added to lack of facilities essential for rapid work, caused anxious and annoying delays. He briefly summarized his impressions from a practical and theoretical consideration of this condition as follows: 1. Embryological, pathological, and clinical facts indicated that this condition should not be interpreted as congenital, and that it would be better termed infantile pyloric stenosis. 2. For practical purposes, the condition should be looked upon as presenting three stages, viz., simple spasm of the pylorus, spasm and hypertrophy of the pylorus, and tumefaction and stenosis of the pylorus. 3. The diagnosis of the first and second stage was extremely important, as it was possible in these stages that medical and dietetic measures might be of curative value. 4. Medical and dietetic measures should not be tried too long and divulsion be resorted to before the hypertrophic stage was reached. 5. The hypertrophic stage reached, gastroduodenostomy, in two sittings if necessary, should be the operation of choice.

Specimen of Pyloric Stenosis Occurring in a Child Eleven Years Old.—Dr. John Rogers presented this specimen. The history given was almost exactly the same as in the case presented by Dr. Fischer. A posterior gastroenterostomy was performed without the loop. The child did well for awhile, but on the seventh day a stain was noted on the dressing, and the gut was found to be prolapsed. This was reduced. For five days all went well, but on the thirteenth day the patient began suddenly to vomit, symptoms of peritonitis developed, and the child died on the fifteenth day. The intestine was found to be adherent to the dressings, and there was a slight adhesive peritonitis. No pus was found in the peritoneal cavity. The gastroenterostomy wound was found to be in perfect condition.

Dr. Charles Herman asked if the case presented the usual conditions. Many cases got well without interference, because fortunately they did not all go on to stenosis.

Dr. Arnold Sturmdorf said that some cases showed only a spasmodic condition of the pylorus and nothing else. Many cases, no doubt, had been reported as cured when they had not been the subjects of pyloric stenosis at all. An early diagnosis was all-important; if diagnosed early enough, the divulsion operation could be employed. The Loretta operation was applicable only to the spasmodic forms.

Dr. Louis Fischer said that the diagnosis of meningitis had been made before he saw the child. The vomiting and emaciation had been extreme and, therefore, in order to save the child, he proposed the operation. He recalled another case in which the child died of inanition.

Dr. Rogers said it was safer to do this operation in one stage than to attempt it at two sittings. The button operation was an impossibility; it might become clogged, or would be too large to pass through the intestine. They were reduced practically to the suture operation. The quickest operation was gastrojejunostomy.

Circumscribed Edema.—Dr. F. S. Meara reported the case of a male infant, one year old, who, up to seven weeks ago, had been perfectly well. He then had an uneventful attack of measles and, two weeks later, he had a convulsion, which was attributed to cutting teeth; this again occurred three weeks ago, or two weeks after the first. The present illness was attributed to a meal of cabbage and potatoes given the child one day before the onset. The day following this delectable meal, a red spot appeared on the left leg; the next morning the baby awoke screaming and the mother found the left leg swollen, "as if it would burst," right up to the groin. This lasted one day. Among the points of special interest was the clear history of what might be assumed as the exciting cause of the onset,

the meal of cabbage, the massive character of the swellings, and the great area involved in each. Practically the whole body was affected in its course. It was also of interest to note how it passed from limb to limb and then to the body, and how each fresh outbreak occurred in the morning, and how brief was its existence. That it should have been mistaken for a cellulitis by a hasty observation was not surprising. The evidences of visceral involvement were not many, but the anuria and the small amount of albumin suggested at least a congestion of the kidneys, with, perhaps, some acute degeneration. The diarrhea might have been due to a similar process in the wall of the gut, but colic seemed to have been absent. The child escaped laryngeal involvement. The child certainly had incipient rickets, and the two convulsions were but another sign of this condition, an explanation which seemed more probable than to assume an involvement of the brain substance in an edema, as had been reported in some cases.

Dr. Herman Schwarz related the history of a child who had attacks of edema every three or four weeks. The severe colic that the child experienced was a point of interest, and the pain was not controlled by anything but the use of morphine. In addition to pain there was vomiting of a clear fluid. As much as 200 c.c. was vomited at one time, and this fluid contained considerable albumin. The urine was absolutely negative, and there was no rise of temperature with the attacks. The stools were never watery during these attacks. He had never succeeded in obtaining a piece of the stomach mucosa prior to an attack, although the child had been kept on a vegetable diet for three or four weeks. Much serum and coagulated albumin were found in the intestinal contents. There was no hereditary factor. Angioneurotic edema might follow the use of antitoxin. He also referred to a case in the literature in which the lung was involved 115 times. The edema might last from fifteen minutes to three hours.

Dr. Beer said that he believed that they were discussing two different diseases, giant urticaria and angioneurotic edema. He thought Dr. Meara's case was one of urticaria.

Dr. Charles Herman spoke of a case of circumscribed edema of the upper eyelids. There was neither pain nor constitutional symptoms during the edema. He had seen two cases during the past year and did not think the disease as rare as was supposed.

Dr. Meara, in closing the discussion, said that the case reported was interesting, and that nearly all cases that he knew of occurred in adults. He said that a patient might have urticaria at one time and massive edema at another. So far as he knew, there was no agreement among authorities in regard to these two conditions. The same process might manifest itself in different ways in neurotic subjects.

Stated Meeting, Held April 12, 1906.

Dr. Matthias Nicoll, Jr., in the Chair.

A Case of Sporadic Cretinism.—Dr. E. Mather Sill presented this patient, a little female cretin baby, ten months old, with a perfectly normal appearance. When seven months old the child weighed 10 pounds, was 24 inches in length, head circumference was 15½ inches, and the abdomen measured 17½ inches. The tongue protruded and there was an umbilical hernia. The skin was dry and wrinkled and the eyelids were puffed up and the whole face had a swollen appearance. The hair was coarse and dry. The child had snuffles and a cold most of the time, and was unable to sit alone. The child never smiled and always appeared dull and stupid. Thyroid extract was given in increasing doses. The child now appeared bright and active and could sit alone, laughed and tried to talk. The tongue did not now protrude. The head measured 15¾ inches in circumference, the abdomen 16 inches, the length was 25 inches, and the child had gained more than three pounds in weight.

A Case of Microcephalus.—Dr. Sill presented this patient, a child fourteen months old, large and well developed, who was brought to him when nine months old because of not being able to sit alone or hold its head up. The child was markedly well developed except the head, which was microcephalic. The ears were large and there was slight strabismus and a stupid expression. The sutures and fontanelles were completely closed. Labor was easy. Parents were healthy. Now at the fourteenth month the child was little if any improved in its mental condition. The question arose as to whether this was a case of premature ossification of the bones of the skull, or whether there was a disease of the brain substance (porencephalon), or whether there was primarily an arrest of development of the brain substance. Dr. Sill believed this to be a case of premature ossification of the skull bones causing an arrest of development of the brain. The advisability of operation here arose.

A Case of Mongolian Idiocy.—Dr. Sill presented this patient, 21 months old. The parents were well. The mother had eight other children, all healthy. She had no miscarriages. Four of the children died. The first child was 18 years old, in good health, and in the eighth month of pregnancy. With the second child the mother was injured and the baby was born dead. The third child died when seven weeks old from pertussis. The fourth child died of gastroenteritis when three months old. The patient was born blue and did not breathe for one half hour. On the third day had a convulsion and had always been weak since and always had a cold. The child was poorly nourished, pale, anemic, with small, cuboid head, the anteroposterior and lateral diameters being equal. There were widely open fontanelles, dry, waxy skin, the eyes of Mongolian type. The mouth was open, the tongue protruded, and the child had an idiotic, stupid expression. The ears were large, the chest rather small, the abdomen large. The little finger was short and had an inward curvature. The thumb was short. There was a great laxity of the joints and ligaments. The muscles were flabby and the child could not sit alone. The palate was highly arched and the two lower incisors were just pushing through the gum. There was atelectasis at the base of the lung and some congenital disease of the heart. The child smiled but was stupidly affectionate and easily amused. The hemoglobin percentage was considerably below the normal and the red blood count was markedly diminished. Mongolians were very backward in their growth. The outlook in these cases was pretty hopeless and they were a constant care and burden to their parents.

Dr. Henry Heiman said that the majority of these cases of Mongolian idiots died of some pulmonary affection. He called attention to the use of thyroid extract in differentiating between cretins and Mongolian idiots; if improvement followed its use for three or four months one could assume the cretinoid condition, or a mixture of the cretinoid and the Mongolian imbecile condition.

A Case of Amaurotic Family Idiocy.—Dr. Isadore Goldstein presented a female baby, aged eight months. There was no history of consanguinity, imbecility, epilepsy, tuberculosis, lues, or alcoholism in either parent or ancestor. The child had a normal birth and was breast fed. When five months old the mother noticed that the child differed from other children of same age; she could not sit up or hold the head erect. The physical examination showed a well nourished child, but inability to support the head and back. The anterior fontanelle was open (3 cm.) and bulging. The child was stupid, with an empty and listless expression. The eyes rolled and there was a horizontal nystagmus. The left pupil was larger than the

right. The fundi showed the characteristic grayish white patch in the macular region, in the center of which was a brownish red, sharply defined oval spot. There were perforations of both drums and deafness. There were chewing movements of the mouth, some difficulty in swallowing and an occasional stridor. There was a right lateral lordosis. Muscles and reflexes were normal.

A Case of Amaurotic Family Idiocy.—Dr. GOLDSTEIN also presented this case, a female child, aged fourteen months, with a history very similar to the first case presented by him.

Dr. G. D. SCOTT said that some of the so-called feeble minded children appeared to be so because of the presence of perforated drum head or some retardation in development. Cases appearing to be idiots often were but feeble minded.

Dr. HENRY HEIMAN said that these cases were all typical and classical. The children were born in a perfectly normal manner and remained normal for five or six months. In order to differentiate between the feeble minded and idiots it was necessary to examine for the characteristic macular appearance in the eye, as referred to by Dr. Goldstein.

Dr. CHARLES HERMANN said that the majority of the reported cases came from America; they were more often recognized here than abroad, and yet he believed many cases were overlooked. These cases belonged to the group which Gowers had described as congenital vulnerable nervous structures.

A Case of Pernicious Anemia.—Dr. SARA WELT-KAKELS presented the history of a child, eleven years old, who was brought to the Mount Sinai Dispensary last February. The skin was very pale, with a slight icteric tinge. The mucosæ were pale. There was slight edema of the eyelids and about the ankles. The lymph nodes were enlarged. The pupils were dilated but reacted to light. The cardiac dullness was increased, extending to the right border of the sternum. The apex beat was in the normal position. There were loud, anemic murmurs over the entire area, especially at the base, and in the great vessels of the neck. The heart's action was 96. The abdomen was distended but the liver not enlarged. The urine contained some bile pigment. No parasites were found in the feces. The red blood cells numbered 1,670,000, the whites 4,300, hemoglobin 26 per cent., and color index 0.84. The differential count of the whites revealed nothing abnormal.

A Case of Persistent Ductus Arteriosus with Incomplete Ventricular Septum.—Dr. SARA WELT-KAKELS presented this patient, a girl three years old. The anomalous condition was found accidentally during a routine examination. When eighteen months old the patient had an attack lasting for a few minutes, during which the eyes rolled upwards and the hands clenched, but there was no frothing at the mouth. These spells occurred several times in the course of the next few months. She was fairly well developed, very bright and lively. There was no cyanosis of skin or mucous membranes. The pulse was 100, respirations 22. Lungs were normal. Thymus dullness was present. The apex beat was rather diffuse and the cardiac dullness extended along the left border of the sternum up to the second intercostal space in the shape of a narrow quadrangle. This increase in cardiac dullness was plainly visible on the shadowgraph. A loud systolic bruit over the apex and even over the base was heard; this was conducted into the left interscapular space and into the large vessels of the neck. It was also distinctly heard to the right of the sternum over a large area and into the abdominal aorta. The absence of hypertrophy of the right ventricle suggested an incomplete ventricular septum. Erythrocytes numbered 6,000,000 and leucocytes 6,800. The abdominal organs and urine showed nothing abnormal.

A Remarkable Case of Congenital Heart Disease.—Dr. EUGENE P. BERNSTEIN presented a specimen of a heart which showed the type of a true mammalian heart, having two auricles and two ventricles, but functionally it was almost a typical reptilian heart, the right auricle being but an antrum for the left auricle, the auricular septum being entirely absent except for a small strand, and no blood could enter the ventricles from this antrum. The right ventricle was but a mere slit in the muscular wall of the left ventricle, having absolutely no function, the conus arteriosus dilating and forming a so-called third ventricle. At the origin of the aorta, under the right aortic flap, was an opening the size of a quill, leading from the left ventricle into the conus arteriosus. Through this small opening all blood to be aerated must pass, and the presence in this opening of a vegetative polypoid mass, tightly adhering to its edge, and almost entirely closing it, probably was the cause of the terminal convulsions and death, acting as a ball-valve thrombus, and closing off the circulation. The left ventricle was dilated, and the walls considerably hypertrophied. The valves were not diseased. The aorta had four main branches coming from its arch. Whether there were any bronchial, esophageal, or pericardial arteries which might have supplied blood to the lungs, could not be determined because of the limited autopsy permission. The blood current, he said, must have been as follows: From the venous system, through the superior and inferior vena cava, to the right auricle, to the left auricle, into the left ventricle, from which place it was divided into two channels, the smaller through the opening under the right aortic flap into the conus arteriosus, pulmonary artery, and lungs, the larger through the aorta to its branches. The case was recorded as a congenital cardiac disease with a polypoid thrombus, two very rare conditions. The disease was not suspected until the child was sixteen months old, and then only because the child was treated for bronchitis. The child lived to be two years and eight months old, a truly remarkable thing with such a heart.

Dr. SARA WELT-KAKELS had a child under observation, one of those blue-black babies, which proved the difficulty in making a diagnosis in these congenital heart cases. A diagnosis of the congenital cases was better made by auscultation than by percussion; hypertrophy might be present, but be compensatory for other conditions present.

Dr. MATTHIAS NICOLL, JR., recalled a celebrated case seen about eight or nine months ago. The child after exercising became almost black, and many men made an attempt at diagnosis. It was found that the case was one with practically one ventricle and two auricles.

A Case of Transposed Viscera.—Dr. BALDWIN presented this case for Dr. Louis C. Ager. The cardiac impulse was found to be on the right, the liver on the left side, but the spleen could not be mapped out. The transposition was verified by *x*-ray.

Deformity of the Chest from Fibroid Contraction of the Lung.—Dr. L. E. LA FETRA presented this case. Especial attention was called to the height of the shoulders, the thinness of the chest anteroposteriorly upon the left as compared to the right side, as well as to the prominence of the scapulæ, showing a lack of development of the thoracic muscles. The case was presented more on account of the deformity of the chest. There was a hollowness under the left clavicle, and the left scapula in particular was very prominent. The chest measured in circumference at the nipple 21 inches; the left side measured, from mid-sternum to spine, 9 1-2 inches; this showed a difference between the two sides of two inches. The apex was displaced to the left almost to the anterior axillary line. The heart sounds were all abnormally loud, and the second pulmonic sound was markedly accentuated, perhaps due to the resistance to the passage of the blood through this left lung. The condition was probably due to the contraction of the fibrous lung and thickened pleura, following an interstitial pneumonia that accompanied the original bronchopneumonia.

There was a bronchiectatic cavity at the lower part of the left upper lobe.

Notes on the "Roof Cure" at the Presbyterian Hospital.—Dr. William P. Northrup told of the overcrowded wards and bad ventilation in this hospital, and said that just one year ago the children were placed on the roof. At once a marked change was noted, in that the children's color became better and they appeared to be far more comfortable. He emphasized the fact that they had, not a roof-garden, but simply a roof. He hoped they would have a roof-garden later. Sun and air were needed, and on the roof they got both.

Pathological Society of Philadelphia.

At a stated meeting held September 27, Dr. C. V. White exhibited specimens of amyloid liver and spleen, as well as a mass of tuberculous mesenteric glands and small intestine, from a case of pulmonary tuberculosis. The liver weighed 4,700 grams and measured 12x10x5 cm. The spleen also was much enlarged. The intestines contained numerous ulcers and in places infected lymphatics could be seen beneath the serous covering. Dr. A. G. Ellis exhibited a specimen of "Lipoma of the Uterus." The neoplasm is an exceedingly rare one in this situation, only eleven instances having been recorded in the literature. The histogenesis is difficult of explanation, inasmuch as the uterus contains no fatty tissue, and the condition lends confirmation to the embryonic theory of the origin of new growths. Dr. M. Howard Fussell exhibited a brain presenting the lesions of basilar meningitis. The spinal cord was similarly involved. The patient was a man who had been under treatment for disease of the ears, and on account of pain and swelling in the mastoid region this portion of the temporal bone was trephined, but without finding disease or affording relief. Dr. A. J. Smith presented a communication entitled "Method of Production of Intussusception." He related a case of metastatic hypernephroma of the bowel, giving rise to intussusception and apparently showing that at least after the process has been inaugurated it is continued in part through the active descent of the serous covering of the inner layer of the intussuscipiens. The specimen presented exhibited two intussusceptions, one direct and the other retrograde, a secondary hypernephroma being present at the apex of each. Drs. A. J. Smith and W. T. Cummins presented a communication entitled "Histological Studies of Rabbits After Adrenalin Injections. Preliminary Report." They pointed out that some of the atheromatous changes observed after injections of rabbits with adrenalin might be due to other causes, inasmuch as similar alterations are not rarely encountered in these animals apart from experimental treatment or other morbid affection. Certain changes in the muscular coat of the arteries and in the lymphatic glands, however, were quite constant in appearance. The cytoplasm of the muscular fibers in the middle coat of the vessels accepted stains poorly and the nuclei were distorted. The lymphatic structure of the glands exhibited injection and hemorrhage.

Toxic Action of Sulphuretted Hydrogen.—Angelo De Dominicis has made a study of the method in which poisoning by hydrogen sulphide kills. He killed dogs rapidly by placing them in an atmosphere of concentrated hydrogen sulphide. Immediately after death he made a chemical examination of the brain and blood to ascertain the amount of hydrogen sulphide present. In the brain tissue there was always a manifest reaction to the gas. In a solution of the blood there was no trace of the gas. The amount of hydrogen found in the brain bears no relation to the amount in the blood, and there seems to be a sort of affinity of the gas for the brain tissue and nerve substance. Its presence in the brain tissues and the peculiar color reactions obtainable with the gas may serve as a means of diagnosis in cases of death from this cause.—*Giornale Internazionale delle Scienze Mediche.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

New Instruments.

AN IMPROVED AUTOMATIC INHALER.

By EUGENE CAROLAN, M.D.,

BROOKLYN, NEW YORK.

In 1897 I had an instrument made called the automatic chloroform inhaler. Experience in the use of this inhaler has led to the adoption of some improvements. I have discarded the towel as a mask and substituted a large wire frame to fit over the face, with a hook attached at its posterior part to connect with the headband. The inhaler now consists of a headband, support, and a large frame mask. The support is a brass bar (nickel plated) shaped at an obtuse angle, one end secured to the headband by a set-screw, the other end having a clamp which keeps the bottle dropper in position. The bottle when in place drops the anesthetic on the mask over the patient's mouth. This bottle is globular in shape, and holds an ounce of the fluid. It is pierced by a tube branching outward into two smaller tubes, one to admit air if needed, the other to drop the liquid. The tube which drops the anesthetic has a little conical pin inserted into it to regulate the quantity of the anesthetic let fall on the center of the mask. It is my custom to regulate it to drop thirty or forty drops to the minute. The mask is large and can be attached to the headband or detached at a moment's notice. This wire frame is covered with stockinette if chloroform is used.

The automatic chloroform inhaler is of special utility in the second stage of labor, when it is necessary to apply forceps or perform version. The manner of application is as follows: Turn the patient crosswise in the bed, apply the headband securely around her head immediately above the eyebrows, attach the support to the headband, put the mask in place, and start the drops as directed above. The patient will be anesthetized in from five to ten minutes to the surgical degree. When one is without an assistant it is advisable to take plenty of time in its application. Producing anesthesia in ten minutes is better and safer than doing it in five minutes. The patient is not to be raised up while in chloroform narcosis. In getting the patient's buttocks well to the edge of the bed, pull on the lower extremities without raising her to a sitting posture. If the patient shows signs of returning consciousness one can reach over from his position in front to start the bottle dropper, and one will observe that it takes very little chloroform to make the patient insensible to pain.

While extracting the child with forceps or performing version I watch the patient's respirations and the color of her face. I occasionally feel her pulse. If the color changes to a pallor or the respirations become irregular I instantly stop the dropping of the chloroform by turning the bottle upward and detaching the mask. I then complete the delivery of the child. If there are any lacerations of the pelvic floor or perineum the patient is sufficiently under the chloroform to permit of their repair in most cases.

According to Schleich, Wedig, and Meyer, chloroform, having a much higher boiling point than the body temperature, stays in the blood longer than the other anesthetics. I believe it, and that is the reason why I prefer using it in labor cases when an anesthetic is called for. When chloroform is administered in the presence of lighted gas jets the room should be well ventilated, since the burnt vapor of the anesthetic yields irritant products, especially carbonyl chloride, capable of inducing pneumonia when inhaled in a concentrated form (Stevens).

The patient while under the anesthetic may, through muscular relaxation, turn the head to one side, and if so the mask stays in position, while the bottle dropper can be pointed so as to drop the drug over the mouth. In case one prefers to have the patient's face turned upward, it is easily accomplished by putting a pillow on each side of the head, thereby holding it steady.

Although I have never lost a case in labor from the effects of chloroform anesthesia, I am just as

careful using it in those cases as I would in the case of a child. Chloroform has a distinct advantage over ether in its more agreeable odor, the small quantity used to anesthetize, the rapidity of its action, and its freedom from exciting emesis.

In lauding chloroform as an anesthetic I am not unmindful of its baneful effects when carelessly used. If a person uses the inhaler under consideration in a reckless manner, permitting the drops to fall so fast on the mask that they cannot be counted, without due observation of the patient's color, respirations, and pulse, it will not take long for him to destroy the patient's life. As the great Samuel Grass said years ago, "Although chloroform is one of the greatest boons that has been bestowed on man for the prevention and alleviation of pain, yet, like every other remedy, it is capable, when abused or injudiciously administered, of producing the most deadly effects." The anesthetizer may meet a case of unusual susceptibility where the inhalation of a small quantity of chloroform produces alarming symptoms; fortunately those cases are very rare. I have read about them, but I have never seen a case of such an idiosyncracy. In fact, I doubt that a few drops of chloroform inhaled will kill a healthy person, notwithstanding the report that Simpson's first case succumbed to the first few whiffs. If we investigate the deaths from chloroform inhalations we find that they occurred in trivial operations, such as pulling teeth in the dentist's chair, oper-

ations on the eyes and throat where the patients were in the sitting posture; therefore the sitting posture is positively interdicted while using the automatic chloroform inhaler.

The experienced anesthetizer may find this automatic inhaler a valuable adjunct to this ahmamentarium. He will notice that the drops fall more steadily and accurately from the bottle attached to the patient's head than from his hand; furthermore, not having to hold the bottle, both his hands are free.

917 Bedford Avenue.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending October 20, 1906:

	Cases	Deaths.
Tuberculosis Pulmonalis	359	174
Diphtheria	194	22
Measles	61	4
Scarlet Fever	89	3
Smallpox	2	—
Varicella	20	—
Typhoid Fever	121	25
Whooping Cough	24	13
Cerebrospinal Meningitis	11	13
Malarial Fever	...	.....
Totals	881	254

Infantilismus with Gastrosuccorrea and Tetanus.—Michele Landolphi describes a case of infantilismus which resulted from gastrosuccorrea of Reichmann's type, and the poisoning from this source produced attacks of tetanus. Infantilismus may be of the type of Lorain, in which it is degenerative and characterized by weakness, small and slender body, and delayed development, with the appearance of an old man. Development, mental and physical, is not arrested, but delayed. This form results from infections, such as tuberculosis, hereditary syphilis, malaria, etc. Intoxications from alcohol and tobacco may lead to it. Another set of etiological factors is connected with defects and lesions of the cardiovascular apparatus. The type of Brissaud gives a true childish form, with big head, infantile stature, and long legs out of proportion to the body. Development is arrested as a result of thyroid insufficiency, and a myxedamatous condition is present. The author's case resulted from autointoxication, due to excessive acidity of the stomach contents, resulting in poisoning which delayed development and caused the tetanic attacks.—*La Riforma Medica.*

The Dosage of Diphtheria Antitoxin.—John Howland believes that diphtheria antitoxin is so innocuous that the unpleasant symptoms occasionally noted after its use may be disregarded. No satisfactory explanation can be given why children with enlarged thymus glands sometimes die after so slight an injury as the prick of a hypodermatic needle. The cases of sudden death that have followed the injection of antitoxin are no more frequent than they are after such trifling injuries in subjects of the lymphatic diathesis. This fact, however, has to be accepted: The untoward symptoms appear as readily after small as after large doses. Severe cases require larger doses, but in any event a mild or severe case requires an increased dosage in proportion to the duration of the infection. Holt's working rule is that on the second day the dose should be twice that of the first for an equally severe condition, and on the third, three times as great. It is theoretically and probably practically better to give the amount which is considered necessary to cure the infection at one initial dose rather than to give small quantities at intervals. For immunizing a child under two years, except the very young, the proper dose is 500 units, and for a child over two years, adults included, 1,000 units. A mild, early attack in a child less than two years of age readily yields to 2,500 to 4,000 units, often to less, but the larger dose is safer. In an older child such an attack would indicate from 5,000 to 6,000 units. A young child with a severe form of the disease, if seen early in the attack, should be given from 5,000 to 6,000 units, the older child and the adult from 10,000 to 15,000 units. Cases, when seen late, require proportionately larger doses. Cases with primary laryngeal involvement require doses of from 7,000 to 10,000 units for the young child, and from 15,000 to 25,000 for the older child and adult. Pneumonia developing early or in cases coming under observation late, should receive very large amounts of antitoxin, from 25,000 to 50,000 units. Pneumonia developing after antitoxin has been given and being due to various microorganisms, cannot be influenced by the specific serum of diphtheria.—*Archives of Pediatrics.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending October 19, 1906:

THE *X*-RAY IN THE STUDY OF CONGENITAL MALFORMATIONS

By JOSEPH WILLIAM PRYOR, M.D.,
LEXINGTON, KY
PROFESSOR OF ANATOMY, STATE COLLEGE OF KENTUCKY

It would be difficult to estimate the value of the *x*-ray as a means of diagnosis. Particularly does this apply to bone injuries, and in congenital malformations it is the only sure means of making an exact anatomical diagnosis. Successful correction is, of course, dependent upon a correct diagnosis.

The most frequent congenital malformation of the upper extremity is that of polydactylism. Annandale has classified these deformities as follows: "(1) A deficient organ loosely attached by a narrow pedicle to the hand (or to another digit). (2) A more or less developed organ, free at its extremity and articulating with the head or side of a metacarpal or phalangeal bone. (3) A fully developed separate digit. (4) A digit intimately united along its whole length, with another digit, and having either an additional metacarpal bone of its own, or articulating with the head of one which is common to it and another digit."

This classification must be extended. The cases to which I will refer cannot be classified under any of these divisions.

While investigating the ossification of the bones of the hand the following cases came under my observation:

Case I.—F. S., male, aged thirteen years, eleven months, and eight days, the fourth child of his parents. The supernumerary digit is between the thumb and the index finger, partaking of the nature of both. It is articulated with the metacarpal bone of the thumb, but the phalanges are those of a finger, resembling the other phalanges in every respect but one, viz., the second phalanx has a distal, as well as a proximal epiphysis. This is the only instance I have ever seen in which there was an epiphysis at the distal extremity of a phalanx.

The metacarpal bone of the thumb differs in the two hands. In the right hand this bone has developed from not less than five points of ossification. The shaft is pronged, the division extending to near the base, where it is fusing. Each section of the base has an epiphysis. The heads of the bone are widely separated. The extra head has an epiphysis. The head belonging to the true thumb may have had an epiphysis, but if so it has united with the shaft. In the left hand the metacarpal bone of the thumb has a single shaft with the distal extremity pronged. This bone has been developed from three centers of ossification, possibly four. The usual proximal epiphysis is present. The inner head, with which the extra digit is articulated is provided with an epiphysis. It is possible there was an epiphysis to the external head; if so it has united with the shaft. It will be seen that asymmetry exists only as regards the metacarpal bones of the thumb, and here we see an attempt upon the part of nature to preserve symmetry, viz., the inner head of each metacarpal bone has an epiphysis and the outer head in each instance is apparently without one.

A comparison of the two hands (Figs. 1 and 2) will show that in every other respect bilateral symmetry is perfect.

The supernumerary digit has the phalanges of a finger. There are three rows, all resembling the phalanges of the other fingers except the second, which has an epiphysis at the distal as well as the usual epiphysis at the proximal extremity. This feature is bilaterally symmetrical, *i. e.* the same condition is found in each hand. In other respects the hands are not unusual. The bones of the carpus and the other bones of the metacarpus and phalanges are developing as usual and are bilaterally symmetrical. Macroscopically the hands are normal, with the exception of the thumb. Abduction and adduction of the thumb and extra digit are synchronous, but limited. Flexion and extension are about the same in each and are synchronous. When I held either one, I could feel the tension of the tendon in the other. I think the extra digit has an extension of the flexor longus pollicis and of the extensor longus pollicis. When I first examined these hands the deformity seemed so great I thought surgical interference was warranted and a correction should be made at all hazards. But after watching the boy at work with a saw and hammer, and the deft manner in which he used a pencil, making good use of both the thumb and the extra digit, I came to the conclusion it would perhaps be best to let well enough alone. For cosmetic purposes there is no question but that the hands could be made to look almost normal. For purposes of utility I am inclined to think that surgical interference is not justifiable.

Case II.—This child is a sister of the one just referred to; A. S., aged eleven years and two days; is the fifth child of her parents. The supernumerary digit is between the thumb and the index finger, partaking of the nature of both. The metacarpal bone resembles those of the fingers, but is devoid of the distal epiphysis. The first phalanx resembles that of the thumb. The second phalanx is abortive, while the ungual phalanx, as regards especially the epiphyses, is that of a finger. All of the rest of the hand is normal. The bones of the carpus and the other bones of

the metacarpus and the phalanges are developing in the usual way.

Notwithstanding this is a case of congenital malformation, bilateral symmetry is absolute (see Figs. 3 and 4). Note the slender phalanges of the thumbs; the crooked distal extremity of the first phalanx of the supernumerary digit; the abortive second phalanx, and the ungual phalanx with the epiphysis; in each hand they are as much alike as any two objects of their kind could be. Bilateral symmetry is to be expected in normal hands. I have seen over and over again that, no matter what the deviation or variation from the usual ossification, the same condition will be found in each hand.

Upon the examination of these hands with the eye, and by palpation, one would think the child had an extra thumb on each hand. Manipulation at the present time reveals which is the supernumerary digit. She has very good abduction, adduction, flexions, and extension of the thumb. The extra digit can only be flexed and extended synchronously with the thumb. When the thumb is held the girl cannot flex the extra digit. On holding the extra digit one can feel the tension of the flexor tendon on contraction of the flexor longus pollicis.

The thumbs are not as large as they should be. I think they would develop if the extra digit were removed. I have urged the father to have the girl's hand corrected, but the parents are ignorant and superstitious, looking upon these malformations as a curse, and I am doubtful if anything will be done until she is old enough to demand it.

The family history, as far as I am able to obtain it, is as follows: The father is living; hands normal, and with no history of malformation in any branch of his family. His mother (grandmother of children) is living, and gave me the history as far as she knew. The mother of the children has been dead for ten years. The father and the grandmother both state that the mother had *"stiff"* thumbs, that is the metacarpo-phalangeal and the phalangeal joints were stiff in each thumb. So far as they knew, the thumbs presented a normal appearance externally. The mother had several brothers and sisters. All had normal hands. None of these live in Lexington, and I could not corroborate any of this except that pertaining to the father and grandmother. There were five children born to these parents. The first three died in infancy. All were polydactylous. As expressed by the father and grandmother, all had an extra thumb, and in infancy they all looked alike. The abnormality was confined to the hands.

I also talked with the physician, Dr. G., who was in attendance at the birth of these children, who said that he had insisted on cutting off the supernumerary digit while the children were quite young and removal would be easily accomplished. I asked him which he considered the supernumerary, and he said it was the outside one that he would have removed. This would have been a very natural mistake. At birth the digits were quite small. There being two thumbs, the outside one would have ben sacrificed, and with disastrous consequences, for the hands of both children would probably have been ruined. Undoubtedly this would have been the case with the girl, in which the outside digit has no carpo-metacarpal articulation. We could not blame the surgeon at that time, as he did not have the use of the *x*-ray with which to make a diagnosis.

I have been interested in the study of these hands more from a biological than from a surgical standpoint. Here is a question of heredity.

Are these morphological conditions transmitted by the father or through the mother? May it not be a blend, or could it be a mutation? and what is the primal origin of these deviations from the

Fig. 1.—Polydactylism; case 1, right hand.

Fig. 2.—Polydactylism; case 1, left hand.

normal? Castle says:* "Every breeder of animals is familiar with the complexity of hereditary processes. He knows that characters of the most varied sort are inherited. These relate not only to general size and proportion, but also to the structure of the individual parts; and not merely to structural, but to functional peculiarities as well. Thus in certain races or strains of animals we find inherited great fecundity, or early maturity, or ability to put on fat or to produce abundant milk; in other cases speed, keen scent, fierce or gentle disposition, and numberless other characteristics are plainly inherited. Very rarely are two heritable traits necessarily associated. The cow with a good flow of milk may or may not be gentle; the keen-scented dog may or may not be speedy. Accordingly we must conclude that different hereditary characters are inherited independently of one another and are probably represented by different structural elements in the sexual element or germ. We know, further, that the laws of transmission of different characters are different, so that we cannot estimate the force of heredity in the lump, but must fix our attention on one character at a time if we wish to analyze the complete processes in operation."

Burbank says:† "In my work with plants and flowers I introduce color here, shape there, size or perfume, according to the product desired. There is not a single desirable attribute which, lacking in a plant, may not be bred into it. Choose what improvement you wish in a flower, a fruit, or a tree, and by crossing, selection, cultivation, and persistence you can fix these desirable traits irrevocably. In the course of many years of investigation into the plant life of the world, creating new forms, modifying old ones, adapting others to new conditions, and blending still others, I have constantly been impressed with the similarity between the organization and development of plants and human life."

This is not foreign to the subject we have under consideration. In my investigation in bone development I have been enabled to determine that bone deviations or variations are heritable. To illustrate this, I find that the chronological ossification of the bones of the carpus may present a number of variations. No matter what this may be, the same condition will be present in the hands of *all* of the brothers and sisters. In rare instances there is a proximal epiphysis to the second metacarpal bone. In something over two hundrd families I have found it present in six. When this epiphysis is present it will make its appearance early in the second year and will unite with the shaft between the eighth and tenth years, although the union with the shaft may be delayed several years later. The presence of this epiphysis is a *family characteristic*. It is far more of a family characteristic than external characteristic, such as resemblance in features, etc., in that it is *always* present and will be found in the hands of *all* of the brothers and sisters. The extent to which this is transmitted and other details are to be worked out in the future.

FIG. 3.—Polydactylism; case 2, right hand.

FIG. 4.—Polydactylism; case 2, left hand.

The starting point for congenital malformations evidently differs with the character of the deformity. When the condition is unilateral we can understand that the variation or deviation could be purely embryonic, occurring in any of

Popular Science Monthly, July 1, 1906.
†*Century*, May, 1906.

the three stages, blastemal, chondrogenous, or osseogenous (?); consequently it is not necessarily heritable.

When the malformation is bilateral, although it may not be symmetrical, it is evidently a heritable character originating in the germ cell of the parents, one or both. We know that the chromosomes of the male pronucleus and the female pronucleus are equally distributed by the mitotic process of fertilization; each contains heritable characteristics. It is an interesting but extremely difficult question to determine the sources and laws which govern these morphological deviations, be they observed in bone or in other tissues.

THE IMPORTANCE OF THE TREATMENT OF CHRONIC OTORRHEA.*

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

OTOLOGIST TO GOUVERNEUR HOSPITAL; LARYNGOLOGIST AND OTOLOGIST TO MT. SINAI HOSPITAL DISPENSARY; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, ETC., ETC.

Someone has said that the individual with a chronic otorrhea is always standing on the brink of a volcano, and without doubt such a statement graphically represents the status of the patient with this affection, as with but little or no warning, various highly important structures may be consecutively infected and a fatal issue rapidly supervene. The importance of the treatment of this condition is therefore a most vital one, and it is desired here to emphasize somewhat in detail the various forms in which otorrhea may be a serious menace to the life of the individual.

Gowers has shown that in 173 cases of cerebral abscess, 102 were the direct result of suppuration of the middle ear, and the Registrar-General of England reports that there are from 300 to 400 deaths reported annually from middle-ear disease, without taking into consideration the probably larger number reported as dying from other causes but which are primarily of aural origin. These statistics certainly manifest one phase of the necessity for the careful treatment of chronic suppurative otitis media in every case, however mild the symptoms may be. The other aspect for insisting on such treatment is the development of deafmutism in the very young or varying grades of impairment of hearing in those of more mature years; the constant danger to life from the presence of a suppurative focus in close proximity to vital organs; and the impairment of the general health so commonly present in the great majority of such cases. On the other hand in cases of otorrhea which have been properly cared for and treated upon sound antiseptic, surgical principles, a fatal termination is most unusual, and the hearing is conserved, while no deleterious effects are observed upon the general health, inasmuch as the suppurating focus has been entirely eliminated.

As the mastoid cells and tympanic cavity are in direct communication by means of the aditus ad antrum, suppurative processes in the latter chamber are practically always accompanied with more or less deviations from the normal of the mucous membrane lining the numerous and complicated cells of the former, and in addition to this the various portions of the temporal bone and especially those portions commonly involved in the usual suppurative process are brought into close relationship, not only one with the other, but also with the interior of the cranial cavity by means of the small venous channels which traverse the bone in various directions. By these means it can readily be seen, therefore, that the spread of the pus collection in the middle ear is greatly favored, and, further than this, greater or lesser degrees of carious necrosis are invariably present in every long-standing case, so that dangerous areas may thus be involved.

Another fact which is of great importance in the development of some of the most serious complications of otorrhea, those due to infection of tissues within the interior of the cranium, is the change which takes place in the mastoid cortex after long-continued middle-ear suppuration, whereby this portion of the temporal bone is greatly augmented in thickness and density so that the tendency of any extension of purulent process in the tympanic cavity is in the direction of least resistance, which in such cases is inward rather than outward, in the direction of the brain and in the larger sinuses in relation with it, through the thin and often partially deficient osseous tissue of the inner mastoid wall.

Destruction of the mastoid interior is by far the most frequent result of untreated otorrhea, and, while this in itself necessitates extensive operation, it not rarely implies other and even more serious complications. As a not uncommon result, therefore, of the untreated otorrhea, phlebitis and thrombosis of the smaller veins in relation with the diseased parts is produced and either the large venous channels, such as the sigmoid sinus or consecutively the jugular vein lower down in the neck, becomes the seat of purulent thrombosis. As a further result of this condition the patient suffers from the absorption of the toxic products rapidly being generated in these parts, and in addition to the original suppurating ear, general symptoms of a septicemic nature make their ap pearance, or should the process be of a still higher grade, pyemia ensues, with the development of metastatic abscesses in the pulmonary areas, joints, or elsewhere, if the patient survives a sufficient length of time; or the septic symptoms are more profound; and what at first was a small focus of pus in the tympanic cavity has now eventuated into a fatal issue. In this same manner a perisinus abscess may also form in connection with the sinus phlebitis, or the pus may follow a downward course and require additional incision into the cervical tissues for its removal.

As indicating the further importance of treat ing otorrhea, the risk that the brain tissue, its meningeal coverings, and the blood-vessels in relation to it undergo is not by any means a slight one, as has in part been pointed out. Localized areas of meningitis in direct relation with the upper and inner walls of the temporal bone are not infrequently brought about by the direct extension of the purulent process in the middle ear, either through erosion of intervening osseous tissue or by means of clefts, the result of incomplete closure of bony areas especially in the roof of the attic, and through which the dura mater is brought into immediate contact with the mucous membrane lining of the cavum tympani. It is quite probable that in a considerable number of cases of chronic otorrhea small subacute areas of inflammation of the meninges are more or less

*Presented at a meeting of the Harlem Medical Association, May 2, 1906.

frequently present, and do not attract attention until the infection from the middle ear has been increased or the patient presents a diminished resistance, when recognizable meningeal symptoms become prominent. Serous meningitis, although rare, may be brought about by the same cause, and more frequently a basal or diffuse purulent inflammation of the brain envelopes takes place, with all its serious consequences.

When the area of meningeal infection from the otorrhea is limited in extent and a protective wall of adhesions is formed around it, an epidural abscess develops in close relationship with the point of infection from the middle ear, and usually in relation with the temporal lobe of the cerebrum. Even more serious purulent collections may develop, however, and a subdural abscess form, or the pus may be entirely isolated in various parts of the cerebrum or cerebellum. More than one brain abscess may be present following an apparently harmless otorrhea, and the diagnostic features thus become correspondingly confusing, while operation becomes futile on account of the great difficulty or impossibility of recognizing the presence of the multiple pus collection.

As before mentioned, caries and necrosis of the ossicles or temporal bone is present in the greater majority of cases of chronic aural suppuration which have not received proper care, and in more severe types the destruction of tissue may be most extensive, the mere presence of a long-continued untreated otorrhea, being in itself strongly suggestive of caries of a part of the ossicular chain, or of the adjacent walls of the tympanic cavity, especially of the attical regions. Should the carious process involve the inner tympanic wall, purulent inflammation of the labyrinth and other portions of the inner ear will ensue, with, in some cases, complete exfoliation of the cochlea; if the roof of the attic be involved, an intracranial abscess in this region is apt to follow, while posteriorly the mastoid region suffers, and rarely when the floor of the tympanum is involved in such a process the large vessels may be opened spontaneously with rapid and fatal hemorrhage; while not uncommonly the medial plate of the mastoid becomes carious and the pus escapes into the soft tissues of the neck.

Practically always avoidable by early treatment of an otorrhea, is the development of cholesteatoma. Its destructive results, by mechanically producing purulent retention and aiding in the destruction of osseous tissue, are essentially phases of a neglected suppurative otitis. When this condition of excessive epithelial proliferation has once been inaugurated, it adds considerably to the difficulties of treatment, and often is the determining point in rendering operation here a failure when the conditions otherwise would indicate a successful issue.

Owing to the course of the facial nerve being in close proximity to the tympanic cavity and the fact that its bony covering over the horizontal portion of its course, often presents dehiscences so that the nerve is in part exposed, paralysis of the facial muscles supplied by it may be produced by the neglected otorrhea, and unlike the paralysis occurring in acute otitis, it is apt to assume a more serious aspect and presents a greater degree of permanency. It may also result from destruction of a portion of the facial canal by the carious processes previously described, and in these cases the abolition or reduction of the function of the nerve is the result of pressure upon its trunk from inflammatory products, or actual inflammation of its structure.

In addition to definite forms of septic intoxication, the general health of the individual with an untreated otorrhea is usually below par, his tissue resistance is decreased, and the dangers of such a condition being uncared for is well exampled by the action of insurance companies in considering the subject of otorrhea a dangerous risk, although the applicant may otherwise not show any evidence of disease.

As regards the hearing, aural suppuration is the most frequent factor in the production of various grades of deafness, and in practically all cases of untreated otorrhea, some degree of diminution of auditory acuity will be found present. While other causes than otorrhea are most active in the production of deaf-mutism, yet suppurative ear diseases play a most important part in a considerable number of such cases, and one cannot be far wrong in believing that in this particular class, the proper treatment of the suppurating ear at an early stage, would have enabled such individuals to have retained their hearing power, and consequently their loss of speech would have been unnecessary. When the tympanic cavity is still suppurating, the impairment of hearing is the result of obstruction to the passage of sound waves, from the purulent material and débris present and also from the actual destruction of soft and osseous tissues, while in those cases which have ceased discharging after a long period of time, the hearing is lessened by the results of the osseous destruction, and in addition, by the vicious cicatrization which has taken place, binding down the remnants of the ossicles, occluding the oval window, and producing irregular cicatricial bands of the greatly altered mucous lining of the tympanic cavity.

From the study of the usual course of otorrhea, it will be found in the untreated cases, that a definite morbid course is followed, leading to the disorganization and destruction previously described. Commencing with the usual and well-known inflammatory changes of the mucosa of the tympanic cavity, with swelling and infiltration, the periostium is involved and then at a later date the bone undergoes carious alteration, so that in every case of any standing, well-known morbid phenomena, all tending to destruction of tissue, may be found. Unlike abscess formation in other portions of the body, but similar to that in osseous cavities, the otorrhea does not tend towards resolution and is not self-limited. It does not tend towards resolution, on account of the obstacles to free drainage, which every untreated case presents on account of the nature of the local infective process and, also, as the result of the inherent tendency of purulent inflammations of the middle ear to successfully involve poorly nourished parts of the bony enclosure. For the same reasons, otorrhea is not self-limited, and, especially is self-limitation restricted as the result of the anatomical conformation of the tympanic cavity with its numerous osseous recesses, reduplications of delicate mucous membrane, and direct connections with the complicated cell structure of the mastoid process. Both these latter aspects of this subject are also enhanced by the nature of the microorganismal infection in the particular case, as a definite bacterium or rather group of bacteria, are usually

found bearing a close relationship to the amount of destruction of tissue and progress and rate of the extension of the otorrhea.

Unfortunately, many cases of otorrhea thus neglected, destroy considerable areas of highly important structures with but little or no symptoms other than a slight discharge, and at times even this may be absent, so that this feature in itself forms one of the strongest arguments in presenting the necessity for the careful treatment of every case of purulent otorrhea even in the absence of any of the symptoms indicating serious trouble. And finally, in contradistinction to the gravity of the case when untreated, is its benign character when properly cared for and the removal from the patient of the ever-present danger when there is suppuration of the middle ear and its adnexa.

45 East Sixtieth Street.

THE SUPPRESSION OF TUBERCULOSIS.

By JOHN BENJAMIN NICHOLS, M.D

WASHINGTON, D. C.

In a general campaign against any communicable infectious disease two elements are concerned, the invading parasites and the invaded host. Consequently, in such campaigns two general lines of effort are available: first, to destroy or prevent access of the causative germs; second, to increase the personal resistance of the menaced individuals so as to render the parasites impotent to produce morbid effects. The measures that will be effective vary according to the conditions presented by each particular disease; in some cases exclusion of the parasites, in others increase of personal resistance, in still others a combination of both methods being indicated.

Yellow fever is an example of a disease in which destruction or exclusion of the germs, by destruction of the mosquitos carrying them, has proven feasible and signally successful in eradicating the disease. Control and purification of water supply accomplish much in reducing typhoid fever. Scarlet fever has been materially reduced by the institution of quarantine measures. With other diseases, however, quarantine seems incapable of making any great impression on the aggregate number of cases, either because the disease is spread during the incipient period before recognition of its contagious character is possible, or because cases occur so mild as to be unrecognizable and yet are capable of spreading the infection. Of such character are measles and whooping-cough; even with diphtheria the results of rigid quarantine have been found disappointing.

Of the second method of eradicating disease by the increasing of personal resistance, a conspicuous example is afforded in the case of vaccination against smallpox; if we had to rely on quarantine alone the prevalence of this disease would probably be little affected, and it would probably be as common as measles is; but vaccination practically eradicates it or reduces its consequence to that of a minor affection.

The applicability of these two general methods to the prevention of tuberculosis may now be considered. Fortunately, the increasing of personal resistance is a factor of high effectiveness against tuberculosis. Under present conditions tubercle baccili are ubiquitous, everybody is exposed to infection, and nearly every one at some period of life harbors a tuberculous nidus. Those of good nutrition and body vigor easily and effectually overcome the infection, and it is only in those permanently or temporarily lowered in condition that tuberculosis can gain a foothold and progress. As marked success in treatment of established cases results from raising the body nutrition and vigor, much more can be expected in prevention of the disease through similar lines of endeavor. There is a large promise of results in reducing tuberculosis by increasing personal resistance.

House and shop sanitation, and the improvement of housing and working conditions as especially needed among the poor, are of great importance to the accomplishment of this end. The providing of ample light and sunshine, plentiful supply of pure air and proper ventilation, suppression of dust, avoidance of overcrowding, proper heating, and cleanliness are essentials along this line. The difference in the incidence of tuberculosis between the country and the city shows what could be done if the environment of the urban populace could be approximated to rural conditions. An abundant supply of pure and nutritious food is another essential to the maintenance of the grade of body nutrition necessary for successful resistance to tuberculous invasion. The problem of the general reduction of tuberculosis is closely bound up with industrial and economic conditions, since upon these conditions the masses are dependent for the means to obtain an adequate food supply. The price of food is an important factor; an increase in food prices means that the man with a limited income not correspondingly increased can provide his family only with a proportionately diminished amount of food. It is not impossible that the general increase in the death rate from pulmonary tuberculosis that has been going on since 1902 may be partially due to the increased prices of food supplies prevailing. The recent combinations and schemes by which excessive prices for food have been maintained and huge fortunes accumulated by a few individuals have undoubtedly exacted a toll of human lives which must stand as a charge in the account against the extortionate monopolists. Cheapening of the food supply is, therefore, an element of importance in the warfare against tuberculosis.

Turning now to the methods looking to destruction or exclusion of the invading tubercle bacilli, the most radical measure possible would be the compulsory quarantine, isolation, or segregation in colonies of the afflicted individuals, as is done in the case of leprosy, a disease similar to and no more contagious or worse in character than tuberculosis. This is a plan not as yet seriously contemplated for tuberculosis. There is no certainty that its adoption would abolish the disease. Tubercle bacilli emanate from and are scattered by animals and birds as well as man. The quarantine for a brief period of a limited number of individuals with acute contagious diseases involves no great hardship; but the permanent segregation of a considerable proportion of the community, the sundering of families, and the breakup of businesses, as would be necessitated in general isolation of consumptives, would be a matter of profound social consequence, to be determined upon not by physicians, health officials, or philanthropists, but only by the general public, after careful consideration of the situation and judgment whether the prospective benefits were worth the price that would have to be paid.

The maintenance of ample sanatoriums for the shelter and care of tuberculous patients in all stages of the disease accomplishes results along the line of quarantine, since all patients collected in such institutions are thereby segregated from the community and a measure of protection to the public is afforded corresponding to the number of cases thus voluntarily isolated.

Every tuberculous subject going about in the community and pursuing his affairs and avocation necessarily to a certain degree constitutes a public menace and a center for contagion. Measures short of complete and general segregation must therefore proportionately lack in effectiveness. Certain measures of this imperfect character are, however, available and advisable.

One such is the disinfection of apartments occupied by tuberculous individuals, especially after being vacated by the latter. This is in common justice due the succeeding occupants. It is not shown that any large proportion of cases is acquired from rooms previously inhabited by consumptives, and no great effect on the general incidence of tuberculosis is, perhaps, to be expected from this measure. Segregation of tuberculous inmates of hospitals and other public institutions may obviate possible contraction of the disease by the other inmates and patients, who, in their weakened condition, are in a receptive state for tuberculous infection.

Proper care and disposal of the sputa in order to prevent dissemination of the bacilli is obviously a measure that should be rigidly and universally practised and enforced. The greatest expectations have been entertained as to the results to be obtained from this measure, and many put the utmost confidence in its power to effect the practical eradication of tuberculosis. Yet the most plausible theories often fail to work out when put in practice, and in spite of the increasing application and understanding of this measure by the general public, the general death rates from pulmonary tuberculosis have in the past few years remained stationary and even increased.

Control of milk and food supply to prevent the use of infected milk and meat is another means of preventing access of the bacilli.

At the present time a great deal of activity is being devoted to a popular campaign of education as to the means of treating and preventing tuberculosis, with the idea that general knowledge of the matter will result in better prophylaxis and therapy and a lessening of the disease. The advantages to be obtained are not unmixed with unfortunate results. The first effect of the staring announcement, "Consumption is contagious," in the educational circulars is the development among the people of phthisiophobia and an unreasoning cowardice rather than a reasonable prudence. While the consumptive patient owes the public the duty of protecting it as far as possible, he himself is entitled to some consideration, and to be treated with aversion and shunned like an outcast adds greatly to his burden and may effectually bar his chances for recovery. Dismissed from his employment on account of the panicky objections of his associates, he loses the income that may be necessary to provide the means for overcoming the disease or to maintain the members of his family in good enough condition to enable them to resist its invasion. Excluded from boarding and lodging houses, he may be forced to resort to places of inferior accommodations when he needs the best he can get to aid in the struggle against the disease.

Recently the movement has become general in this country for the health offices of the various cities to engage in systematic efforts to limit the spread of tuberculosis on the basis of the registration of cases. The objects aimed at are laudable in the highest degree and could be objected to by no humane persons. Nevertheless, the movement has, with the fullest knowledge of the practical needs of the situation and the most conscientious motives, been opposed by respectable sections of the medical profession on the ground of ineffectiveness and of embodying unnecessary and mischievous features; and in spite of the fact that this opposition is flippantly criticised and denounced by oracular philanthropists, it is of sufficient consequence to deserve respect, and the question is still worthy of consideration.

Obviously, the mere registration of cases of tuberculosis in the health offices of itself accomplishes nothing; it is a subsidiary and auxiliary feature, a means to an end; and if that end can be as well gained in other ways, it may be a clumsy and useless means. Yet the idea of a (secret) list of consumptive patients in the health office has so fired the imagination of some enthusiasts that they have come to regard it as *per se* a powerful agency in the eradication of tuberculosis, and have formed an extravagant estimate of its value. Obviously, it is what registration leads to that is of importance, and the claim is made that registration of all the cases gives the health officials "control" of the situation and of the disease. We find that the measures taken and the "control" exercised by the health officials consist in, first (unless otherwise requested by the attending physician), the sending of circulars of information to the patients, with perhaps a visit once a year or thereabouts by a nurse or semiamateur inspector; and, second, the disinfection of apartments after death or removal therefrom of tuberculous patients (which requires a distinct system of notification). That the distribution of circulars—and that to patients under the personal care of practising physicians—constitutes "control" of tuberculosis is inane grandiloquence. The results to be expected from it (as is shown by actual trial) are trivial and insignificant; one might as well undertake to dig the Panama Canal with a teaspoon as expect to eradicate tuberculosis by such means.

The measures concerned in the registration system as generally practised, involving as they do a certain amount of espionage over patients and physicians, and interference with and supervision of private practitioners, are necessarily of a bureaucratic and paternalistic character. While individual prerogatives must give way before the general welfare and peculiar public exigencies, nevertheless, in a society organized on an individualistic basis, the centralization of power and the restriction of individual activities should be reduced to the minimum compatible with the accomplishment of the essential ends sought. Police ordinances regulating expectoration, obligatory disinfection of apartments occupied and vacated by tuberculous patients, supervision of milk and other food supplies, enforcement of proper house and shop sanitation, the care of indigent consumptive patients, the maintenance of sanatoriums for indigent and pay patients—all these are legitimate objects for state and municipal activity. With regard to self-supporting and well-to-do patients able to provide for their own care and under the treatment of their own physicians, the conditions are different.

Unless the practice of medicine is to be definitely and systematically put on a bureaucratic or socialistic basis, the supreme control in cases of this sort must be vested in the attending physician, and interference and invasion of his province by public officials is unwarranted. This supremacy is recognized by the registration laws as adopted in many cities. It is difficult to see any difference in practical effect between the system of compulsory registration of all cases of tuberculosis and permitting the health department to take action only in such cases as the attending physicians so designate, and a system of optional registration, in which the physicians report those cases in which they desire to obtain whatever aid or service the health office may be able to render. Precisely the same cases are brought under the action of the health department under both systems. Yet one system involves a bureaucratic element, to which, while not likely to prove any material burden, many physicians have felt an instinctive repugnance, and which could, if executed in a captious and autocratic way, become a means of unmerited harassment. If the two systems are alike in practical results, the compulsory and bureaucratic feature would seem to be unnecessary, and the agitators who denounce the optional system as utterly ineffective thereby record themselves as holding the belief that the secret list and the infliction of penalties (the only essential differences between the two systems) are not only real direct preventive agencies, but also the principal agencies by which they expect tuberculosis to be eradicated.

The statistical value of the data obtained through general registration is adduced as a point in favor of such registration. Such statistics would no doubt be of interest, but only in an academic way; in some respects they would be unreliable, and could add nothing to our practical knowledge of how to treat the cases. The acquisition of useless knowledge (even for the benefit of the altruistic dilettanti) would not seem to warrant the imposition of a system of penalties and bureaucratic machinery on the public and the profession for the sake of obtaining it.

A tendency to the assumption of paternalistic functions in municipal health offices is distinctly observable, especially in the cities of the largest size. This is evinced in various directions, among others in connection with tuberculosis in the free examination of sputum for all persons, regardless of their ability to pay. This is frank paternalism, of the same order as, and with no more justification than, would be the providing of public physicians to make free physical and clinical examinations of applicants apprehensive of possible tuberculosis. Free sputum examination (except for the poor) is not essential to the ends to be gained by registration measures, and is an invasion of a field properly belonging to private practising physicians. Precisely the same reasons which justify it would warrant the paternalization of the entire practice of medicine.

The final criterion of the efficacy of the registration and allied measures must rest on the results of actual trial. In nearly all the cities quoted as examples of the system, registration has been introduced too recently, or has not been executed with sufficient vigor, for any results yet to be accomplished; their experience is, therefore, valueless as evidence of its efficacy, and the claims of their officials as to its value have no foundation or weight. In only one or two cities has the registration system been given sufficient trial for its practical results to be determinable.

In New York City the system has been in operation since 1894, or twelve years, a period long enough for its utility to be tested. During that period there has been a marked decline in the death rate from pulmonary tuberculosis in that city, and this decline is claimed to have been due to the measures taken by the New York Department of Health. This claim has been iterated and reiterated as an evidence of what can be accomplished toward the eradication of tuberculosis by systematic municipal action. A critical examination of the results in New York will, therefore, show what may be expected from such action.

The results claimed in New York City from the efforts of the Department of Health are concisely set forth in the following words (Annual Report, New York Department of Health, 1902, pages 29-30), referring to the decrease in the death rate from tuberculosis, especially among children under fifteen years, since 1892:

"It [the decline in death rate] indicates in the most striking manner the unexpectedly successful results of the preventive measures adopted by the department in relation to this disease. . . . The education of consumptives and their families as to the careful disposition of expectoration, the renovation and disinfection of apartments occupied by consumptives, and the removal of many consumptives to properly equipped institutions have accomplished this result."

All the credit for the decline of tuberculosis is claimed, without reservation, for the Health Department. It stands to reason, however, that the thousands of practising physicians in New York City must have had some part—a great part—in the reduction of the tuberculosis death rate, through personal institution of efficient modes of treatment and sanitary preventive measures. The claim of the Health Department is, therefore, manifestly extravagant and excessive, and until the extent to which the efforts of the practising physicians may have contributed to the result can be determined, no estimate whatever can be formed of the efficacy of the measures taken by the municipal medical officers.

In the accompanying Table I. it will be seen that from 1881 to 1890 or 1895, prior to the introduction of the Health Department measures, there was a much larger decline of the tuberculosis death rate in New York City than has taken place since. Before it can be demonstrated what effect the Health Department measures have had, it must be shown that the causes that lowered the death rate prior to the introduction of those measures did not continue to operate to lower the rate after their introduction.

I.—Average Annual Number of Deaths (by Five-year Periods) from Pulmonary Tuberculosis per 100,000 of Population.

	New York City (Boroughs of Manhattan and the Bronx)	Buffalo
1881–1885.....	398	210
1886–1890.....	350	204
1891–1895.....	286	172
1896–1900.....	256	110
1901–1905.....	237	125

In the third place, as shown in Table II., the decline of the tuberculosis death rate in New York since the introduction of registration measures has simply been parallel to the decline in the

country at large and in other localities. In New York in 1900 the consumption death rate was 84 lower than in 1890 (or 24.7 per cent.); in the "registration area" of the United States from 1890 to 1900 the decline was 64, or 26.1 per cent. As compared even with the District of Columbia, which is held up as the horrible example of municipal and professional remissness in this matter, the decline in the death rate in the District, without registration, has been practically the same as that in New York since registration was instituted there.

From these considerations it appears that not only is the claim of large results from municipal measures in New York not substantiated by a critical analysis, but it is not shown that those measures have made any material impression whatever on the death rate from pulmonary tuberculosis in that city.

*Registration of tuberculosis cases instituted.
†Census year.

In the city of Buffalo registration was instituted in 1897; so far from decreasing, the consumption death rate in that city has been higher ever since.

Those enthusiasts who have the idea that it will be comparatively easy to stamp out tuberculosis have no conception of the enormous difficulty and magnitude of the task. It does not follow (as often assumed) that because a disease is communicable it is therefore easily preventable. Tuberculosis is of the dimensions of a mighty natural force, an example of the indifference of nature to individuals when the benefit of the race is concerned. It is a disease preeminently of the weak and inferior, and through it the weaklings and unfit are eliminated. Many of those saved from tuberculosis fall ready prey to other diseases, especially pneumonia; and of recent years, coincident with the decrease of deaths from consumption, there has been a large corresponding increase of mortality from pneumonia. The lessening of the consumption death rate is, therefore, largely an illusory and not a clear gain, many of those saved from it dying of other causes.

Contemplation of a limited field only may lead to erroneous conclusions and post-hoc-ergo-propter-hoc fallacies as to the preventability of tuberculosis. On comparing different places we find great diversity in the death rates from the disease; thus, Buffalo has a rate far below the average, while New York and Washington have rates far above. This diversity is obviously due to differences in local conditions, and is not necessarily a matter of either credit or blame for the local medical profession. On comparing the statistics of different cities and States for a period of years, a certain annual parallelism is shown to exist in the mortality from tuberculosis; this indicates that general conditions (meteorological, economic, education of the profession and the public) operate as well as local (and entirely apart from local methods) to influence the incidence and mortality of the disease.

Since the discovery of the tubercle bacillus twenty-five years ago, there has been an enormous decrease in the mortality from tuberculosis; this has apparently been due to the application by the medical profession of knowledge of the cause and effective methods of treatment of the disease gained from laboratory investigation and clinical observation. It is the rank and file of the medical profession that is necessarily most concerned with the tuberculosis problem and the actual detection and management of the cases. They have the practical knowledge and training to meet the requirements of the situation. The philanthropic motives and public spirit of the profession are beyond impeachment. The efficiency of their methods is shown by the results gained in the past. Nevertheless, there exists a strong tendency in certain quarters to ignore and depreciate their position in the matter, to withhold or give to others the credit due them, and to exalt amateur and paternalistic methods.

None are more earnestly desirous of the suppression of tuberculosis than are the medical profession; none are laboring more effectively to this end. The help is needed of all who can assist in the movement. Nothing, however, is to be gained by hysteria, blind following of fashion, self-seeking officialism, or unpractical amateurism, or by any other than sane, rational, and scientific effort.

1321 Rhode Island Avenue.

REMARKS ON ENUCLEATION; SOME UNCALLED-FOR DISFIGURING OPERATIONS RESULTING FROM FAILURE TO RECOGNIZE ACCESSORY SINUS DISEASE.*

By HENRY MANNING FISH, M.D.,
NEW YORK.

The ocular symptoms resulting from an affection of the accessory sinuses of the nose have attracted a great deal of attention during the past few years, and various theories have been announced to explain their pathogenesis. According to Ziem they are manifestations of a passive orbital hyperemia from a faulty oxygenation of the blood resulting from a hindered nasal respiration—a nasal stenosis from edema, polypi, puru-

*Read by invitation before the Sections of Ophthalmology and Laryngology of the Medical and Chirurgical Faculty of Maryland, Baltimore, February 23, 1906.

lent secretion, etc. As this hypothesis fails to account for a circulatory disturbance limited to the ocular region as well as the instances in which there is no "hindered nasal respiration"—the nostril presenting a practically normal appearance as it does in some cases—the writer has modified the above theory and considers the stasis in the periorbital circulation to be the result of a vasodilatation resulting from an irritation of the sympathetic by the secretion pent up in a closed sinus. This theory is based on Gurwitch's demonstration, that the vasasupraorbotalia, frontalia, ethmoidalia, and ophthalmofacialia carry the greater portion of the venous blood from the nostril and its sinuses into the ophthalmic vein, and the fact, as shown by Zuckerkandl, that the upper walls of the various cavities, situated at the base of the brain, are pierced by minute openings through which the lymph and blood-vessels pass, thus affording a direct communication between the circulation in these cavities and that of the meninges, some of the blood-vessels entering the convolutions of the brain. An intracranial circulatory disturbance results in cerebral symptoms, as vertigo (one of the early and most constant phenomena of sinusitis), epileptoid attacks or unconsciousness (Lichtwitz, Engelmann, Mayer, and the writer), or it may produce meningitis or abscess of the brain. A stasis appearing in the orbital circulation may cause an edema of the lids, or an exudate behind the globe with resultant protrusion, or it may show itself in any of the eye tissues. If it appears in the cornea, for instance, there may follow an elevation of the epithelium, abrasion, infection, and corneal abscess, with perforation, and consequent enucleation. Should a severe intraocular involvement take place, and later the fellow eye show inflammatory symptoms, resulting from a sinusitis of the corresponding side, the condition could well be mistaken for one of sympathetic ophthalmia. Such an instance with enucleation, the only one in the literature, has been reported by Ziem, which he says reads like a "fairy tale."

In a man, twenty years old, whose left eye had been enucleated and who complained of a continual left conjunctivitis, Ziem found the following condition in the right eye: concentric contraction of the visual field, marked hyperemia of the papilla, reduced accommodation range and vision 5-12. A few years before there had been headache, heavy dull feeling and pain about the left orbit, with frequent flashes of light and colors noticed in the left eye. The condition varied more or less until four years later, when the patient suffered from an intense left frontal pain, etc., during which he was treated in a hospital for "inflammation of the brain." Several physicians, however, questioned the above diagnosis and attributed the condition to some affection of the left eye, as "it often turned in." Accordingly the patient was examined in an eye clinic, where the reduced vision, quantitative light perception, was attributed to the internal strabismus, and a tenotomy was performed. Later the patient was treated for two weeks in another eye clinic, and the left eye was enucleated "to save the second eye," which "appears to have been done," as was stated, on the patient's clinical card. As the patient had a nasal speech and breathed through his mouth, Ziem at once examined the nose, which was found to be completely occluded by a congestion and an abundant purulent secretion. This was subjected to daily treatment, but, as the condition in the right eye became worse (the field still further contracted, the accommodation range more reduced, the pupil large and sluggish), the antrum was opened, which showed a chronic empyema. Following treatment the visual field improved and the accommodation range and vision were about normal. Ziem again saw the patient, after a recurrent attack during which an iridectomy had been advised elsewhere, the ocular symptoms probably being taken for glaucoma.

In some instances the intraocular circulatory disturbance may not show such serious results, but may manifest itself only by photophobia, reduction of the accommodation range with consequent asthenopia, etc. This last-named condition, given the presence of a foreign body in the other eye, can mimic perfectly the irritative stage of a sympathetic ophthalmia, as in the following personal observation. On July 26, 1904, the writer was consulted by Mr. S., aged forty-four years, who complained of headache, asthenopia, and intense continued photophobia. About four years before, after a severe cold following exposure, he suffered with vertigo, dull headache, left supraorbital pain, and the left eye troubled him; asthenopia, lacrimation, marked photophobia, and dimness of vision. He consulted an ophthalmologist, who, after careful examination under belladonna, diagnosed sympathetic ophthalmia, owing to the presence of a foreign body in the right eye which had been there fifteen years, and who advised the enucleation of the right eye, on account of and to relieve the symptoms of the left. Four other specialists, two in Louisville, were consulted, all of whom agreed in the above diagnosis and advised the same treatment, and finally the patient consented, although, according to his statement, the right eye had been absolutely quiet all this time, and still retained some, though very slight, vision. The patient said the removal of the right eye four years before failed to relieve the symptoms in the left. Examination showed the left lids somewhat red and swollen; conjunctiva slightly injected; media clear; pupil active though sluggish and contracting to but four mm. on throwing a light with a loup on to the retina; fundus normal; vision, with constant correction .75 ax. 90°, 15-20. Actual range of accommodation was not taken, but the statement of the patient of inability to do any close application indicated its involvement. On questioning the patient it was learned that his "headache" consisted of a nearly constant dull pain in the left supraorbital region, and this symptom, in connection with the frequent vertigo and the ocular phenomena, suggested a left frontal sinusitis. Pressure about the left frontal sinus showed sensitiveness; in the left nostril were found polypi and granulation tissue, bathed in a purulent secretion coming from behind the middle turbinate. An abundant secretion was obtained on syringing the frontal sinus, and on the following day the patient voluntarily reported marked relief from the vertigo and intense photophobia, and he said his rest had been much quieter than formerly. Two or three days' treatment resulted in a further improvement, the pupil responding normally to light, contracting to two mm. The immediate and marked relief of all the symptoms in this case demonstrates clearly that they were due directly to the secretion being partially suppressed in the frontal sinus and not to a "reflex irritation" from the presence of the nasal polypi, vegetations, and greatly swollen middle turbinate. The anterior end of the middle turbinate, polypi, etc., were removed and the treatment was continued. The patient reported relief from

the former severe symptoms, especially from the intense photophobia. At the end of a fortnight his constant glass was changed to + 1. D. Owing to the writer's absence the patient was not seen again until November, when the former symptoms were again present, though not so severe. Nasal polypi were removed; further surgical interference was advised, but refused. The patient was not seen again.

An instance of enucleation on account of panophthalmitis resulting from an affection of the nasal accessory sinuses was reported by Rollet. In a patient, three months after typhoid fever, intense periorbital pain, edema, protrusion and destruction of the eye from panophthalmitis for which Panas performed enucleation in 1896. As the orbital cavity still contained a purulent secretion some three months later, it was curetted by Gayet. "When I saw the patient he complained of a continuous purulent discharge from the orbit, pain at the root of the nose, and a nasal discharge, which symptoms were relieved by an opening of the frontal sinus. It is certain that the panophthalmitis was the result of a sinusitis following typhoid."

The ocular phenomena in the above case appeared during convalescence. The generally accepted theory in explanation of the ocular symptoms following typhoid, that they are due to a reduced vitality of the tissues, may account for their appearance during the disease, but, in the writer's opinion, it does not explain those complicating convalescence. Harke has shown how frequently accessory sinus disease is found in typhoid. In each one of three cases of typhoid, complicated by facial erysipelas, Zucarini discovered sinusitis at the autopsy and recommended appropriate treatment in typhoid cases showing facial erysipelas. The writer has had one case of sinusitis appearing in convalescence after typhoid.

Rollet, in addition to the above case, refers to a second patient, "in whom an early operation for sinusitis prevented panophthalmitis." In a personal observation treatment of the sinuses aborted threatening panophthalmitis and probable enucleation, periorbital edema, swollen lids, protrusion of the globe, deep corneal abscess, hypopion, iridocylitis, and blindness. The trouble began over four months before; the corneal abscess was of three weeks' duration, with no response to internal or local treatment. The patient said at the first visit, "Take out the eye if it will do any good." The third day after treatment of the sinuses no hypopion; on the eighth day corneal abscess healed over; later periorbital and retroocular edema disappeared entirely; the globe, with the exception of a corneal scar, assumed a normal appearance.

The imminence of panophthalmitis in this case is shown by the pus in the anterior chamber and the iris adhering to the posterior layer of the cornea. The preservation of a practically normal appearing globe, even though vision is lost, is infinitely preferable to the disfigurement of a glass eye, especially if the patient is a lady. If during the height of the inflammatory condition in the above patient's left eye the right one should also have become congested, would not the condition in all probability have been attributed to a "sympathetic ophthalmia"? The writer, basing his conclusions on the frequency with which he has found internal eye disease to be due to sinusitis, is of the opinion that many cases diagnosticated as sympathetic ophthalmia were identical with the above condition, and the therapeutic measures in many instances failed to give relief, as they were not directed toward the real cause. On the same grounds he would explain why enucleation in panophthalmitis occasionally terminates fatally, the meningitis, as well as the panophthalmitis, being the result of a sinusitis.

The immediate arrest of the pathological process in the above case and the rapid healing over of the corneal abscess and disappearance of the intraorbital edema—lid chemosis and protrusion of the eye—following drainage of the frontal sinus demonstrate conclusively that the condition resulted from an intraorbital circulatory disturbance due to sinusitis, and, in the writer's opinion, it also illustrates the formation of a corneal abscess in accordance with his theory mentioned above. In another personal observation each eye showed numerous elevations of the corneal epithelium from an underlying edema, interstitial keratitis, cyclitis, and vision counting fingers, with restoration to normal by drainage of the cavities alone. This was one of some 12-15 influenza-ocular cases, in all of which, with the exception of two patients who did not undergo treatment as advised, the ocular symptoms were traced by the writer to a sinusitis, as shown by their relief following drainage.

A case of enucleation following influenza was reported by Hodges, and an examination of the orbital tissue showed an inflammatory condition. There had been intense periorbital pain, edema of the lower lid, chemosis, protrusion and rapid destruction of the eyeball. Corneal abscess resulting in destruction of the globe and enucleation occasionally appears in a healthy individual after a severe cold. This happened to a prominent physician in a Western city a year or so ago. "A cold in the head," in the writer's opinion, is but synonymous with sinusitis, and to the latter he would attribute the formation of such a corneal abscess. In six fatal cases of measles Harke found a disease of the accessory sinuses; in each of five cases of measles Wolff found a sinusitis at the autopsy; in each of three cases of measles reported by Hertel, corneal abscess developed—one patient recovered, one had both eyes enucleated, and the third lost both eyes and died. In each patient the purulent nasal discharge was examined to determine the particular microbe doing the mischief, revealing the pneumococcus, harmless to the normal cornea, according to Shumway. A study of the above facts, in the writer's opinion, demonstrates the fallacy of, first, the line of investigation heretofore pursued as to the cause of corneal abscess in these cases; it is not a question as to how the microbes reach the eye, but, rather, what renders the tissues subject to infection by these microbes, harmless under normal conditions; and, second, the therapeutic measures employed—treatment, instead of consisting of local applications, should be directed toward the cause.

An instance in which an enucleation of a normal eye was advised by an ophthalmologist, but was prevented by the timely diagnosis of a sinusitis, was reported by Farlow. In a sixteen-year-old patient a tumor appeared in the inner orbital angle of the left eye which gradually increased in size and pushed the globe forward. Following a severe cold, the eye was closed and protruded still further, for which he consulted two ophthalmologists, one of whom recommended an incision of the upper lid, probably for suspected orbital abscess; the other advised an enucleation. Farlow found no nasal discharge, but considered the

trouble to be due to suppressed sinusitis; intranasal operation (ethmoiditis) was followed by cure. In a case reported by Isola of intense headache, edema of the right upper lid, chemosis and later protrusion, reduced vision, and intense periorbital pain, a possible sinusitis was excluded by a negative nasal finding. An induration between the globe and the orbital ridge was held to be a sarcoma, and the contents of the orbit were removed. The same symptoms, appearing later in the other orbit, were considered to be an extension of the cancerous growth, but, luckily, before exenteration of the other orbit, the original "tumor" was examined under the microscope and found to be a simple inflammatory exudate. That a negative nasal finding does not exclude a sinusitis is shown by Farlow's case, and by many reported by the writer.

An instance of blindness followed later by enucleation due to sinusitis is a case by Berg. In a woman, twenty-five years old, the sight gradually failed until mere light perception remained in each eye, accompanied by most excruciating pain in the head, protrusion of each globe, abundant nasal secretion, at first hemorrhagic, later yellow in color. Nasal examination showed a bulging of the sphenoidal sinus; the right eye was enucleated and the ethmoidal and sphenoidal cavities opened, the secretion from the latter filling the orbit. If the sinusitis had been recognized early in this case, can there be any question that the enucleation could have been avoided and the blindness in each eye prevented as well? This case appears in the "possible list" of the many cases of blindness due to a flow of cerebrospinal fluid through the nostril, collected by St. Clair Thompson. That some of these instances of blindness, due to a flow of cerebrospinal fluid through the nostril, are but cases of sinusitis is shown by a perusal of the case histories, and by Deutschmann's explanation, according to Berg, of their pathogenesis: "The inflammatory matters of the stagnant lymphatic currents in the frontal or sphenoidal sinus penetrate into the subdural and subarachnoid spaces and their ramifications which accompany the optic and olfactory nerves." This hypothesis is probably the result of the generally accepted idea that an optic nerve affection is necessarily of cerebral origin.

There are many instances in the literature of enucleation of an amaurotic eye in order to relieve persistent pain; especially is this so in cases of glaucoma. In the writer's opinion his theory that idiopathic ocular disease arises from a circulatory disturbance caused by an irritation of the sympathetic by a sinusitis applies also to glaucoma, and on reading case histories that terminate by the statement that the sightless ball was removed on account of the persistent pain—cases of intraocular tension excluded—I often wonder whether the desired relief was really obtained.

In the following personal observation enucleation did not relieve the pain. In a lady with double iridocyclitis, increased intraocular tension and vision nearly lost several years before, an iridectomy was followed by very marked improvement in vision of the left eye. Later the right eye, although sightless, was also operated on, in order, according to the patient's statement, to relieve the glaucomatous pain; but on failure the ball was afterward enucleated for the same reason. When seen by the writer this patient complained of continual daily frontal neuralgia on each side, for which she had tried everything, but in vain. Drainage of a secretion from the frontal sinuses was the only treatment, according to her statement, that ever brought about any noticeable relief from her continual torture, and the causative relationship between the affection of the accessory sinuses and the ocular condition was shown by less abundant opacities in the vitreous, and by the vision improving from 1-10, 1-12 to 1-2. This patient herself discovered that the neuralgia was not due to the glaucoma, as she had always been told.

The most striking instance found by the writer, of the awful results following failure to suspect disease of the accessory cavities, is the following case of sinusitis by Bosworth. A man, forty-two years old, "during ten years of hopeless and pathetic search for health, under the advice of physician after physician unavailingly, made a sojourn in Bermuda; went to work, with his hours as long as possible, spent a fortnight in the Middletown Asylum, practised gardening, spent a summer in the Adirondacks, underwent a several months' course of electricity, adopted the Salisbury diet, was operated upon for varicocele, then tried Baucheitsmus daily for three months along the spine, then had eyeglasses fitted for supposed error in refraction, was operated upon for stricture, had castration performed on perfectly healthy organs, underwent circumcision, had his pubic artery ligated, was operated upon for hemorrhoids, had his spine cauterized unavailingly, wore a seton in the back of his neck for a month, had the muscles of his eyeball operated upon, and then had a healthy eyeball enucleated"—a veritable polyclinic subject. Three days after drainage of an accessory sinus disease the patient resumed his occupation, a healthy man. The operation on an external ocular muscle in this case, and in Ziem's also, points to a symptom that occasionally appears in sinusitis, an involvement of an external ocular muscle. This has been noted by Kuhnt, Posey, Hoople, the writer, and others.

Were the ophthalmologist to regard a retroocular edema, the involvement of an external muscle, a sluggish pupil, and an idiopathic inflammatory condition about the orbit or within the globe as a symptom of disease of the accessory sinuses, these unfortunate enucleations might be avoided, and, in many instances, the function of the eye be preserved.

CONTRACTURES AND MUSCULAR ATROPHY

By GUSTAF NORSTRÖM, M.D. (Stockholm),

NEW YORK.

We intend in this paper to study two secondary conditions, which may follow diseases of the articulations and of the osseous and muscular system. These two conditions are contractures and atrophy. In many of them massage is useful. We might even say that it is so in all; but nobody would think of affirming that he can definitely cure contractures, no matter what their origin or cause is. He may effect their disappearance, and it is then a really curative medication; but he may also simply contribute to the improvement of the nutrition of the muscles as a simple adjuvant of some more radical therapeutical means.

On account of the fact that identical treatment directed against symptoms, which in themselves seem to be the same, can yield quite different results, it is indispensable to analyze the cases, to trace them back to their origin, and, if possible, to determine their respective nature.

It is well-nigh impossible to study contractures and atrophy separately; they are two closely connected conditions which often exist either simultaneously or succeed one another. A contracted muscle will in time atrophy; the contrary will also happen. A muscular atrophy is often followed by contraction of the primarily affected muscle, or of the antagonistic muscles. This close relationship does in no way implicate the identity of the two conditions. We may conceive *a priori* that differences exist between them, which may be easily ascertained. It is possible for the nutrition of the contracted muscle to be intact; for all its elements to be preserved, and for sclerosis and fatty degeneration to be absent. In regard to this, the anatomical researches which have been conducted so far have not established definite ideas. Few have been the researches directed towards recent contractures. Then again, examinations by sight and by touch of a region which is the seat of contractures do not always reveal to us that diminution in size and emaciation which characterize pronounced atrophy; contractures and atrophy must therefore be studied separately.

Several years ago Duplay declared that contracture is an acute and necessarily spontaneous spasmodic shortening of the muscular fibers. Charles Richet calls contracture a prolonged muscular contraction which cannot be relaxed under influence of the will.[1] Erb speaks of a permanent shortening of the muscles, which produces a gradual approximation of their joints of insertion. In 1875 Straus gave the following definition: Contracture is a persistent and involuntary tonic contraction of one or several muscles of animal life.[2]

Blocq considers contracture as a pathological condition of a muscle characterized by involuntary and permanent stiffness.

According to the author, quite an appreciable number of conditions, which are similar to contracture, are erroneously connected with it.

In *true* contractures we find a constant exaggeration of the tendon reflexes and an habitual spinal trepidation; the antagonistic muscles are always affected; this contracture often begins under the influence of a traumatism. It exhibits variations in its intensity. On examination of the muscles a sensation of elastic resistance is experienced. It disappears after a certain length of time, which varies a good deal, after applying an Esmarch bandage. It relaxes completely during chloroform narcosis, and the electric reactions of the muscles are normal.

In *false* contractures there is no exaggeration of the tendon reflexes. These are, on the contrary, often diminished and sometimes even abolished. There is no spinal trepidation, the antagonistic muscles are not always affected; there is no tendency to generalization; the traumatism has no influence on its occurrence. A sensation of fibrous resistance is experienced; Esmarch's bandage as well as chloroform narcosis do not modify the condition. In some cases the electrical reactions are altered.

Blocq has done his utmost to find a criterion which would enable him to distinguish true from false contructures.[3] If we admit that the above symptoms adduced by him are correct, there always remains a gap from want of completeness of the general definition. Can we assume that all conditions called false contractures are not endowed with involuntary and lasting stiffness, that in fibrous retractions for instance, these have preserved their elacticity or that they have lost it only for a certain length of time? Be that as it may, alterations universally called contractures, are found in affections of the muscular system, the articulations and of the nervous system, and until Blocq's nomenclature is definitely accepted and his definition precisely stated we have no right to reject some of these changes or to consign them to a complimentary chapter.

We are confronted with facts: Contractures are observed to follow primary affections of the muscles, acute and chronic myositis. We may find contractures, although the muscles have not become affected; it is to these that the deformities and defective attitudes of the limbs after articular affections are due. Blocq considered these affections as a type of true spasmodic contractures. These were described a long time ago by Hunter, who considered them as a sympathetic result between the muscles and the joints. They were carefully studied by Duchenne, of Boulogne, who called them reflex ascending contractures of articular origin. The affected muscles are the seat of more or less violent pains, which he ascribed to a morbid state of the gray matter.

Bell ascribed the defective attitudes to a position instinctively taken by the patient in order to relax the muscles and relieve the pain. Bonnet attributed everything to the pressure exerted by the morbid liquids of the articular cavities on the ligaments. But defective attitudes are found in arthropathies which are not painful; in dry arthritis, when there is no effusion into the synovial membrane; they result from muscular contractures. These are sometimes developed at about the same time as the arthritis itself and are not followed by any appreciable anatomical alteration of the muscles or their neighborhood. There exists perhaps no essential difference between these contractures and those which are observed in some diseases of the nervous system and of which the permanent contracture of the hemiplegic muscles is the prototype. The shortened muscles suffer and their fibers degenerate in time. This is what has been demonstrated by Hermann, Ormerod, and many others. Contractures of nerv-

ous origin were at first explained by such a convenient theory that it has been adopted by many physicians. The muscular fiber possesses in its normal state an activity of its own. This latter maintains the muscles in a state of permanent contraction, it is a muscular tone, a sort of excitation maintained by the spinal centers. The paralysis of a muscle is followed by an increase of the tone in its antagonist. The position of an organ depends upon the equilibrium maintained by all the muscles that support it or impart motion to it. Under this hypothesis, deviations can always be explained.

Saint Germain says: "Nothing is more easy to explain than muscular torticollis. When we examine a skeleton we perceive that the head is in an unstable equilibrium on the top of the vertebral column, so situated that the anterior part of the head, which consists of a portion of the skull and the face, is heavier than the posterior part. This fact, which is very evident in man, is much more so in animals. Thus we see that the head is kept in equilibrium only by the power of the muscles which are inserted into it and which act as shrouds, and, if there is an inequality in the lateral tractions, the equilibrium is soon disturbed. This inequality may, theoretically speaking, be produced either because there is too much traction on one of the cords or because there is not traction enough. Most frequently one of the cords pulls too much and one of the powers becomes predominant while its antagonist remains normal; in a word, the disturbance of the equilibrium generally results from the contraction of a muscle and not from the paralysis of its antagonist."[4]

A great deal might be said on this ingenious theory. It is probably true in some cases of inflammatory torticollis, but in admitting the physiological starting point, namely, the maintenance of the equilibrium by antagonism of the symmetrical muscles, all objections are not refuted. We have seen cases of circumscribed myositis followed by radiation to other parts without any change of place of the head, and this is easy to understand. Excessive activity on the part of one muscle calls forth a reaction on the part of its antagonistic muscle, so that the equilibrium is restored. In contractures of hemiplegic muscles this doctrine is hardly applicable. Why do some muscles contract on paralysis of the lower extremity while others remain flabby and undergo atrophy?

Hüter's theory.—In three articles on this subject Hüter contested the old theory and left very little of it in existence.[5] His ideas have been adopted by Volkmann.[6] Let us see what he substitutes for it. In his "Handbuch der Gelenkkrankheiten" we find a scheme which is so simple that it seems useless to me to reproduce it here. This scheme is to demonstrate the idea which the author had of the movements of the foot. According to him it is a simple lever, whose point of support is nearer the posterior than the anterior extremity. The first one will incline forward when its direction is governed only by the force of gravity, because the anterior arm of the lever is the longer. A deformity will result, which is called talipes equino-varus. If the extremity remains horizontal it will depend upon the intervention of the muscles. If all the muscles are paralyzed, the toes are lowered, the heel is elevated, and the points of insertion of the posterior muscles approach each other. Now the muscular substance possesses an incontestible property. Every time the points of insertion of a muscle are approximated for some time, its nutrition suffers and the muscle will contract. The author says: "This law is confirmed by our anatomical pathological data and by experiments. It is sufficient to wear for several weeks a retentive bandage near a joint. If we have to put up the fractured forearm at right angle with the arm, so that the articulation of the elbow, which is absolutely normal, is immobilized, we shall find, after removal of the apparatus, that the movements in the direction of extension are very limited. In order to convince one's self of the nutritive change all we have to do is to put the patient under an anesthetic and we shall see that we can, without inflicting any violence, reach the maximum of extension." He adds further: "As there are very few cases of absolute and complete paralysis which render contraction of the muscles impossible, an acting force capable of shortening them has been searched for, for want of something better. One has had recourse to the muscular tone. Does it exist? That is to say, can a muscle undergo spontaneous shortening after complete suppression of the innervation? This is a physiological question which we cannot discuss. It is of little importance in the explanation of paralytic contractures. Nobody who believes in the existence of the muscular tone would admit that an agent of so little energy could support the weight of a limb for months and years."

Hüter's objections seem to me more decisive than his theory itself. It is based on one fact which is true only as regards the lower extremity. One would often be embarrassed to explain how the points of insertion of a muscle can get nearer to each other. According to Hüter there is no difference between contracture and atrophy. As soon as the nutrition has become defective everything else is only a question of degree. It is rather difficult by the aid of this doctrine to explain many contractures of muscular origin, which resemble a great deal those that are produced by affections of the nervous system.

Charcot, Vulpian, and Erb have placed in the category of reflex phenomena those muscular affections which were but the expression of a state of the gray substance of the brain, originating from the transmission of articular irritant phenomena through the nervous system. One is thus led to admit that there exists in the medullary substance a certain relation between the cells originating from the articular centripetal nerves and those of the motor nerves of the muscles in which the various observed affections are localized.

Nearly all those who have studied the question have expressed themselves with the same degree of reserve. A perceptible medullary lesion may exist, but it is probable that in many cases the disorders do not progress so far; it is probable that the lesion is limited to a sort of cellular superexcitation which is the cause of the contracture. Like all irritations of the same kind this irritation will soon exhaust the element and give rise to numbness, so that paralysis and atrophy will be consecutive to the initial contracture, if the latter is prolonged. Is this theory final and conclusive? Does it suit all cases? We cannot affirm it. It is difficult to explain contracture of the hemiplegic muscles by a primary irritation of certain groups of medullary cells.

Besides, it matters little. All we can say is that Duchenne's doctrine is applicable in some cases and Hüter's in others. If we ascribe the first stage of the process to the irritation of the medullary cells, we may explain the second one by the nutritive disturbances which the muscle whose extremities approach each other is undergoing. The origin and cause of contracture and atrophy are thus elucidated.

Sometimes real paralysis develops in those affections in which contractures have occurred. It is then that Hüter's doctrine may be applied. Paralysis as well as contracture may terminate in atrophy; but the latter is often developed in articular atropathies from the very onset. In making injections of liquid into the synovial membrane, Mr. Valtat has been able to provoke it without any difficulty.[7] It is generally observed in the peri- or para-articular muscles. It affects by preference those which are used for the purpose of extension. Atrophy of the deltoid is not at all rare after affections of the scapulo-humeral joint. When the hip is affected, it is most often the gluteal muscles that suffer; after diseases of the knee atrophy of the femoral triceps most often occurs. As Vulpian has justly remarked, it is above the joints that the trouble is produced. In most cases it is difficult to adduce long continued rest as an etiological factor and to connect the observed phenomena with atrophy due to inactivity, as it sometimes makes its appearance in a very short time after the starting of the articular trouble. Besides, it would be hard to explain why the extensors are those which alone, or particularly, get affected.

From what we have said one fact is certain, that whatever be the predominant phenomenon, the nutrition of the muscle is always affected. How this is produced is of little importance; whether the general state of health plays a prominent part in the production of the affections or whether the atrophy and the contracture are produced in a direct or reflex way, we may nevertheless interfere advantageously and by persistent local medication we may improve the nutrition of the muscle. This was our object in view.

The following very interesting case will serve as an illustration, although, owing to its particularly grave character, an improvement only was obtained. Mr. Ch., eighteen years old, of weak constitution, has complained for eight years, following an attack of measles, of great weakness in the lower extremities. Patient could walk, but was easily fatigued. The legs gradually seemed to get shorter and the deformity more marked. In 1869 he was still able to extend the right leg, whereas the left leg was fixed in flexion. For three years he had been walking with crutches. Faradization for six months was without effect. In 1880 Dr. Metzger extended the right leg forcibly and applied a plaster bandage. The latter was so painful that it had to be removed, and the patient returned to Paris, where I saw him for the first time in 1881. The lower extremities at that time showed marked contracture, the chief muscles involved being the flexors of the thigh and to a less extent the adductors. The angle of flexion was, in both legs about the same, 130°, which could on the right side be increased to 150° by forcible extension. Active mobility at the knee joint was of practically no functional utility. Pes valgus of the second degree. The contracted muscles of the thigh are of very firm consistency and inelastic. The same holds true for the muscles of the calf, whereas the other muscles of the leg show some atrophy. The knee joint itself is apparently normal. After two months of treatment with massage and forced extension and adduction I was able to extend the right leg completely. On the left side, however, improvement was less rapid and less complete, but after two months of further treatment I noticed with satisfaction that the muscles had regained a great deal of elasticity. Extension could be made to 160°; the adduction also was greatly increased so that the patient was able to ride his horse. By means of an apparatus constructed by Mr. Mariano in Paris, and aided by a stick, the patient could walk. It is reasonable to assume that active exercise as well as the weight of the body producing tension upon the contracted and atrophied muscles, will, at least in a slight degree, decrease the remaining deformity on the left side.

Before taking up massage proper, I used electrotherapy alone in the treatment of muscular atrophy, but I was not satisfied with the latter, and since several years I have given it up entirely. It is sometimes a useful adjuvant, but I ascribe the greatest part of my success to massage. With it alone I have cured cases in which electricity did not give the desired results.[8] It would, however, be a fallacy to suppose that it is always so in old atrophies and especially in those which are secondary to white swelling. In old persons great perseverance is required. We must not be afraid of energetic manipulations, rubbing, kneading, and tapotement; passive movements are also indicated. One of the best maneuvers consists in having the patient execute active movements and resisting them. When the atrophy has reached a certain degree of development, these movements are so feeble that they are of little or no use. In these cases massage must be performed first in order to increase the nutrition and vitality of the muscles, before one may be able to have recourse to the mentioned movements with assistance. The nerves must also be massaged, and it would be well to combine digital pressure, which we have mentioned elsewhere, with the other manipulations. In order to appreciate the results of the treatment repeated measurements must be taken, and at exactly the same level. Care must be taken not to push the measure more on one side than on the other.

The results are, of course, much less satisfactory in contractures and atrophies resulting from an affection of the nervous centers than in those which are secondary to a peripheral alteration of the articulations, the bones, or the muscles.

8. It has been maintained that massage acts only on the atrophy of the muscle, but that it is of no influence on the frequent complication of fatty degeneration; that, in order to overcome this, we must resort to electricity. Without contesting its favorable influence, I have seen cases, even very advanced ones, in which by means of massage alone I was able to overcome the degeneration completely and restore the former firmness and consistency to the muscle or group of muscles.

WHEN IS "EARLY" IN OPERATING FOR APPENDICITIS?

By A. M. POND, M.D.,

DUBUQUE, IOWA.

Just so long as surgeons persist in practising their art by rule, just so long will their work be unsatisfactory and their teaching unwholesome. When a surgeon tries to measure the danger of a ruptured appendix by hours, or still more, to put on such cases a time limit after which the inflamed organ becomes dangerous, the dynamics of pathology has not been reckoned with. The gravity of all infections is dependent upon (1) the virulency of the infective agent, whether it is simple or mixed, and (2) the degree of physical resistance possessed by the individual.

It is most unfortunate, then, to have the teaching of eminent men expressed in hours. These men, to whom we owe respect and a great debt of gratitude for the pioneer work of blazing the trail that should be the means of saving human lives, no doubt expected that instead of following their diction of "early" and "late" operation, the physical findings would prevail rather than any fixed rule as to the number of hours that should have elapsed; but naturally, being observant men, they had figured the number of hours since the initial symptoms of the attack, and then recorded their pathological findings as revealed by operation.

Usually the patients who are operated upon in the first twelve or twenty-four hours of their attack recover, and again we are surprised sometimes at the serious pathological condition revealed in the cases giving a history of but a few hours. The following case is an example of what was considered the first attack, and of what promised to be an early operation:

Paul B., aged ten years; American. Had the usual diseases of childhood, viz., measles, chickenpox, whooping-cough. October 12, 1903, he was taken with sudden pain in the stomach early in the morning, but did not awaken his parents. He ate a moderate breakfast of oatmeal, toast, and coffee, and went to school. At 10 A. M. he began to vomit and was excused from classes. I saw the patient at 10.30 on that day. He was anemic and nauseated; the vomitus consisted first of the stomach contents, then of a frothy, yellowish mucus; temperature, 98.6°; pulse, 84. The pain had begun near the umbillicus, was spasmodic in character, and had gradually become more severe in the right iliac fossa. Examination revealed a rigidity of the right rectus muscle produced by percussion; gentle continuous pressure, however, could be tolerated to a considerable extent; examination per rectum revealed an exceedingly tender spot by making pressure to the right. Diagnosis was made of an acute appendicitis. The parents were exceptionally intelligent people and expressed a willingness to cooperate with me in every possible way. All food was denied, an ice-bag was placed over the tender spot in the right inguinal fossa, and the boy was put to bed. At 1 P. M. I saw the child again; at that time the pulse was 96 and the temperature was 100.6°; the abdomen was more rigid and the attacks of pain were more frequent. Operation was advised at once, and at 4 P. M. the abdomen was opened, revealing a thickened, hyperemic appendix, which was kinked upon itself, and the tip of which was adherent to the posterior part of the cecum. The appendix contained pus and a small concretion about the size of a small bean, and the mucosa of the organ was gangrenous.

This patient was operated upon inside of the first twelve hours of the attack; the formation of pus, therefore, must have been very rapid.

During the recovery of the boy he remembered having a sharp "stomachache," as he termed it, once before during the early part of the summer; he vomited at that time, but attributed the attack to the eating of green apples, so did not mention it to his parents. It is interesting to note in passing that two symptoms with which the attack was ushered in continued until after the operation; these symptoms, pain and vomiting, I consider very important; in fact, I am coming to attach more importance to their occurrence, severity, and character than I am to the pulse rate and the degree of temperature; however, I would not wish to be understood as in any way ignoring the value of the latter.

I have no doubt there is a large percentage of cases of acute appendicitis with a history similar to the foregoing, cases in which a catarrhal attack had preceded, leaving either a stenosis of the canal of the appendix or a small concretion. These cases are prone to recur, and when they do we find, as in the above case, that damage has already been done to the mucosa; and the formation of pus, with the symptoms of an active infection, is very rapid, and sometimes attended with quite obscure symptoms.

In comparing the mortality rates in a series of operations made by men with large clinical opportunities we are at once struck by the fact that cases which were operated upon within the first few hours of the attack as a rule end in recovery, and that the mortality increases after twenty-four hours up to seventy-two hours, then subsides again; hence the dictum has gone abroad that the first twenty-four hours is the most favorable time to operate in these acute cases, but I feel that it is wrong to put this great lesson in hours or minutes, or even days.

The security shown by these tables of recoveries is not dependent upon the hour at which the patients were operated upon, but is rather dependent upon the degree of pathological disturbance that had existed or had been interrupted; and since it takes a few hours to produce these pathological conditions, it seemed most natural to express the danger point in that manner. There would be little or no objection to the use of the time limit if other elements were equal. There is no doubt that, in cases where the infective agent or agents are the same, and the degree of physical resistance is the same, the hours of development to a grave state would be the same. But how are we to know these things? We have not as yet any instruments of precision that can measure the virulence of an infective agent, neither do we have any method of determining the physical resistance to exact degrees. The examination of the blood for its relative values of leucocytes, red cells, and hemaglobin may be a step in that direction, but as yet we know nothing of the degree of resistance of the cell structures of the body. Hence, I believe that the expression in hours of a safe time for operation in the acute cases of appendicitis is most unfortunate, and is too apt to be followed blindly without the due regard to the real demands for operation, which are the recognition of the pathological progress, as evidenced by the patient's condition.

The first symptom to appear, and the first symptom of importance, is the pain, the character, and the location of which may well be studied, because it has to do directly with the pathology of the part; it owes its very presence to a diseased condition of the organ, and frequently there is a very close relation existing between the pain and the degree of dis-

turbance; the more severe the pain the more grave the pathology.

This is only true, however, of the appendix that remains intact, for as soon as a perforation occurs, the distended appendix is relieved and the pain ceases; the absence of pain, then, is certainly not a good omen.

The character of this important symptom is at first colicky, and as a rule it recurs periodically; the location is at first at or near the umbilicus, and after a few spasms of pain nausea or the second cardinal symptom becomes conspicuous. The pain gradually shifts into the lower portion of the abdomen, usually into the right fossa, but sometimes into the left, and rarely to a point above the bladder. As the pain becomes more constant it usually becomes more intense, and as its intensity increases the nausea is more frequent and more severe; with the increasing pain and nausea there is usually a local peritonitis that can first be detected by percussion of the right fossa; a distinct spasm of the right rectus can be felt before any marked rigidity can be detected by gradual pressure. The symptoms, then, can be classified according to their occurrence, and I am convinced that they occur in exact relation with their importance. Pain, then, is the first and the most important symptom, followed closely by nausea and vomiting; the increased pulse rate and rise in temperature are evident in exact proportion to the pathological progress in the appendix or peritoneum; the rigidity of the abdominal wall follows this damage and is Nature's attempt to protect a peritoneum that either has already become inflamed or is rapidly becoming so.

The gravity of an acute inflammation of the appendix is due not so much to what damage may be done to this vestigial organ, as to the dangers of local, general, or diffuse peritonitis caused by the rupture into the free abdominal cavity of its highly infected contents.

Undisputed cases of catarrhal appendicitis have been reported by eminent medical men as cured, and there is no doubt that little if any pathology would be in evidence if the appendix could be examined, but there is usually some damage done to the mucous lining of the organ that perverts the normal currents of the appendix; the lumen is either lessened, or perhaps obliterated, or there is an extravasation of blood or serum into the canal which unites with the inorganic substances of secretion, and promotes cohesion which forms a nucleus for a concretion. The presence of this concretion, then, becomes a constant source of irritation and there at once arises the question of the equation of resistance and infective virulence. So long as the resistance is greater than the infective ability of the invading host, so long is the integrity of the part maintained; but with a lessened blood supply or lowered support from any cause the structure of the organ is compromised and degeneration or destruction takes place in exactly the proportion that the increased activity of the infective agent bears to the physical resistance of the part, be it much or little.

An appendix containing a concretion or having a stenosis of its lumen is, to a certain extent, in a constant state of hyperemia, and dissolution may take place in a very few hours. A local peritonitis producing the acute pain, the vomiting, increase in pulse rate, and rise in temperature with abdominal rigidity cannot be called early in the attack with anywhere near the security that one would like to feel in operating in these cases that have been under observation perhaps but a few hours, and which, according to the time standard, would be called early. When we find in any case adhesions, with local peritonitis of varying degree, an appendix containing pus, concretions, or even a stenosis of its lumen with a gangrenous mucosa, it surely is not early in the course of the disease, even if the presence of the latter has been known but a few hours, nor is such a case likely to give the promised prompt recovery we would like to expect.

Therefore I would offer an earnest plea that the cardinal symptoms produced by the pathological processes taking place in the structure of an organ be given the precedence over the matter of hours, and the proper importance be put upon these symptoms, irrespective of the time of their occurrence.

THE MODERN TREATMENT OF INTRACAPSULAR FRACTURES.

By W. L. HUNT, M.D.,

BANGOR, ME.

VISITING SURGEON EASTERN MAINE GENERAL HOSPITAL.

THIRTY years past, when the writer began to read medical journals, there was a controversy whether intracapsular fractures ever united. The same discussion has entered more or less into all the medical textbooks since. In a general practice of many years numerous cases of this fracture have come under my observation. Some were seen with counsel, all were carefully diagnosed, and to all the same statements were made, that they would be probably crippled for life. Many patients survived for years, able only to sit up or hobble on crutches; some died soon after the injury. I never saw an undoubted case in which the patient was able to walk until after Dr. Ruth's paper was read at the Saratoga meeting of the American Medical Association in 1903. Since then I have seen three patients, and they are all walking without a limp. The object of this paper is to give details of these cases.

Mrs. K. was eighty years and six months of age and blind. She tripped on the stair and received a fracture. She was under the care of Dr. Swett and Dr. Caro Swett of this city. I saw her on the third day after the injury. She was thin and had a cough, some fever, and beginning bed sores. A fatal prognosis had been given. Dr. Maxwell's treatment was given after she had been etherized, and she was assiduously attended by the Drs. Swett until her recovery. A water bed was used with fine effect on the bed sores. She had a long and tedious illness, due to the cough and resulting weakness, but in a few months made a very good recovery, and was around in four months, complaining more of the knee than of the hip. She was too ill some of the time to move the knee-joint sufficiently. The leg is some shorter than its fellow, but the patient walks without a limp and is alive and well to-day. This boon she owes to the Maxwell treatment.

While this case was in progress I saw the second case with my son, then a medical student. Mrs. E., residing on a farm, had lifted her grandchild on her knee to hoist him in a wagon when she fell and the neck of the femur was broken. She was etherized and a diagnosis made, and Maxwell's method was used. She had no trained nurse. She was seventy-five years of age, short, of medium weight, and in good health. She had some mild fever, no bed sores, and as she lived some way out of town was not often seen. The knee had no exercise and was quite stiff on the patient getting about. In forty days the splints were taken off. She also is alive and well and has no limp. The leg is about an inch or less shorter than its fellow.

The third case completes the list of the intracapsular fractures I have seen since 1903. This lady was between eighty-one and eighty-two years old. She fell in the doorway or was pushed over by a cart and broke the femur. She was thin, with red cheeks and thin skin. She was etherized and a diagnosis made. Her son, a prominent physician of Oldtown, was notified and she was removed to a relative's residence, where her son saw her. She was again given ether and Dr. Maxwell's method was instituted and carried out with the aid of a trained nurse. The treatment was discontinued after about forty days and she began to get around. For some months she had trouble with the knee-joint, as here also it seemed impossible, from various causes, to move the knee sufficiently often to prevent some ankylosis, but in six months she was going around as usual. She has no limp and her degree of shortening has not been measured. She goes everywhere and no one would suspect she had ever injured her hip.

After using the old treatment one is agreeably pleased to see how easy it is to keep the patient clean and free from bed sores and how comfortably the bedpan can be handled. The patient can raise the body as the weight of the injured limb is balanced by the traction of the side pulley. By this method a severe injury is turned into a milder one and one not usually fatal except in the very debilitated. The treatment is not widely known. It comprises the old downward extension with adhesive straps with side traction at the groin, carrying a pull upward, outward, and forward. This takes up the weight of the thigh partly, holds it opposite the point of fracture, and draws the capsule like a tight sleeve over the fragments, holding them in place.

This method should be widely known and generally practised. Its originator was Professor Maxwell of the Keokuk Medical School. It was brought prominently before the profession by an admirable paper by Dr. Ruth of the same city.

A METHOD OF OPERATING ON THE LIP.

By C. F. BUCKLEY, M.D.,
BROOKLYN, NEW YORK

THE illustration herewith presented shows, diagrammatically, the method employed by the writer for the removal from the lip, under local anesthesia, of

benign growths or of those that are malignant but without glandular involvement. It is equally applicable to any operative work upon the lips where general anesthesia is not demanded, and even there it will, I believe, be found to be of advantage.

For the purpose, a pair of Murphy intestinal anastomosis clamps, with their blades sheathed in rubber tubing to protect the engaged skin and mucous membrane from the effects of their serrated surfaces, are applied as indicated, with their edges about three-eighths of an inch from the line of proposed incision. The local anesthetic is injected, and the portion of the lip containing the growth, *A*, is then excised. Sutures are inserted at points *B-B*, the wound edges are approximated, the clamps removed, and the dressing applied.

The advantages of this method are:

1. The application of the clamps prior to the injection of the anesthetizing medium confines the drug employed to the area to be operated upon, rendering systemic absorption impossible. This permits of complete anesthetization of the tissues between the clamps and an absolutely painless excision of that part.

2. Complete arrest of hemorrhage from the coronary arteries.

3. The handles of the clamps may be used in approximating the wound edges, thus relieving tension on the sutures.

4. No assistant is required. The necessity under which the writer once was of operating entirely alone on a growth involving the lower lip was the originator of this idea, which has been used successfully since that time.

802 CARROLL STREET.

Eucalyptus Oil as a Vermifuge in Ankylostomiasis.—Llewellyn Powell Phillips believes that the treatment which he here describes is more successful than that with thymol, in such doses as can be given in safety. When properly carried out, it is followed by very good results. The formula which he uses is composed of: eucalyptus oil, 2.5 grams; chloroform, 3.5 grams; castor oil, 40.0 grams. The routine method which he employs is as follows: About six o'clock in the evening the patient is given a saline purge; he fasts all night, and the next morning at seven takes half of the above mixture. The other half is taken thirty minutes later. The patient stays in bed still fasting until the bowels move. If any depression is noticed after the administration of the first dose, the second one is omitted. In young boys and feeble, anemic patients the dose is divided into thirds, and given at twenty-minute intervals. The dose may be repeated every other day. As a rule three or four liquid stools follow, though in some cases there is only one. Occasionally the first administration is not successful. The chloroform is an essential constituent of the formula, as has been proved in cases in which chloroform water was substituted by mistake. The treatment has been employed in one hundred and three cases, forty-four of which were entirely successful. In twenty-six of these cases the treatment was efficient, while in the other thirty-three the results were either unknown or negative, the drugs being employed in some for diagnosis, while in others mixed treatment was adopted. One patient died. The results show that the treatment is satisfactory with reference to its vermifugal effects. It is not unpleasant for the patient, for long fasting is not necessary and the taste of the mixture is not offensive. The stay in the hospital is shortened. The absence or rareness of cardiac depression is a good feature. The writer adds that oxyurides are freely expelled by it, and he has used it in one instance to expel a tapeworm, with success.—*The Journal of Tropical Medicine.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 3, 1906.

A SOCIETY FOR THE IMPARTIAL INVESTIGATION OF NEW REMEDIES.

A NUMBER of members of the medical and pharmaceutical professions met at the Hotel Astor in this city on October 21, 1905, and established the American Pharmacological Society, with Dr. Reynold Webb Wilcox, of New York, president, and Dr. F. E. Stewart, of East Orange, N. J., secretary. The object of the society was announced to be the promotion of progress in the knowledge of medicinal drugs and chemicals, and the dissemination of that knowledge for the relief of human suffering. This object is to be attained by a collective investigation, conducted under the authority of the society, evidence for and against the value of new remedies being gathered from all authentic sources and published in the working bulletins of the society. The function of the society, it is stated, is not to pronounce a verdict regarding any remedy under investigation, but to publish all the evidence obtainable, leaving the medical profession to act on this evidence as judge.

The plan under which the society works was originally suggested to the Smithsonian Institute in 1881 and was endorsed by many individuals and societies. A few years ago a joint committee was appointed by the American Medical Association and the American Pharmaceutical Association for the elaboration of this plan, but the only result of the conference was the appointment of the Council on Pharmacy and Chemistry of the American Medical Association, the methods of which differ materially from those originally suggested in that the working-bulletin system is omitted and the feature of standardization is accented. In order to restore this important part of the original plan and to remove the element of secrecy from the investigation, this new society was established. Its first working bulletin is published in *American Medicine* for October, 1906, and deals with a product recently condemned by the Council on Pharmacy. From the evidence, analytical and experimental, collected and published by the Pharmacological Society one would be led to conclude that the condemnatory action of the Council on Pharmacy was precipitate. The society mentions the report of a sub-committee of the Council, but states that it cannot include the report in its bulletin since the results of the experiments of the committee have not been made scientifically available by a publication of the names of the investigators and the methods by which these results were obtained.

So far as can be determined by a careful study of this first working bulletin, the plan of the society would seem to be one that deserves the confidence of the medical and pharmaceutical professions. The society works in the open, the evidence pro and con is accepted on its face value, all the facts regarding the drug are placed before the profession, and the latter is left free to form its own judgment after weighing these facts. That is what the physician needs. He wants to know whether the remedy offered for his use in practice is as it is represented by the manufacturer, and if not, what it is. He can then decide for himself whether the preparation is good or bad, and does not need a committee to decide for him. The American Pharmacological Society apparently has a work of great utility before it, and if it continues in the impartial manner of its first essay it will certainly deserve the confidence and the thanks of both physicians and pharmacists.

THE TOXIN-ANTITOXIN UNION, IS IT CHEMICAL OR PHYSICAL?

AT a recent meeting of the Society for Experimental Medicine and Biology, Dr. Field of this city reported some interesting studies which he and Dr. Teague had made on the character of the toxin-antitoxin combination. As is well known, the components of a chemical combination, the ions, carry opposite electrical charges, and when such a combination is dissociated by electrolysis the two kinds of ions travel to and accumulate at the two poles. In the case of a number of proteids it has been found that the pole at which they accumulate depends on the reaction of the medium. Whether this holds true of all proteids, and especially of native proteids, is open to question.

In the experiments of Field and Teague a number of technical difficulties which had proved sources of considerable error in the work of previous workers along this line were cleverly overcome, and it was found that both toxins and antitoxins (diphtheria and tetanus) traveled to the cathode pole. Moreover, this direction was not changed by an alteration in the reaction of the medium; at least this was true of the native products. These results, while rather surprising, appear to be amply confirmed by the numerous experiments of the authors. They conclude that the union of toxin and antitoxin is not a chemical one, and hold, with Nernst, that it is probably an adsorption phenomenon. If this is true, the consequences will be far-reaching, for the entire side-chain theory of Ehrlich is built up on the assumption that the union of toxin and antitoxin is strictly a chemical one. It is because of this assumption that Ehrlich finds no difficulty in explaining the specificity of the reaction products in immunization. How this can be done with the adsorption theory remains to be seen.

We are informed that Dr. Field's paper is to appear in an early issue of the *Journal of Experimental Medicine*. Its publication will be awaited with interest, as will also the reply that Ehrlich's school will make to this bold attack on their fundamental position.

PERITONITIS OF DOUBTFUL ORIGIN.

In addition to the large number of cases of peritonitis in which the infection can be traced to one of the abdominal or thoracic organs without any question, there is another smaller group in which the source of the trouble is more or less obscure. Two possibilities may be considered in accounting for the latter form—a focus of infection is present somewhere in the body, but so far removed from the peritoneal cavity that a direct extension of the process is impossible, or the peritonitis itself, in the absence of any organic lesion, constitutes the only demonstrable pathogenic process in the organism. The first of these, which may perhaps be included with such types of peritonitis as are found in connection with articular rheumatism and scurvy, has been thought to be of a hematogenous origin, a few isolated germs reaching the peritoneum through the blood stream. The second class is represented by the much-disputed primary idiopathic peritonitis, in which the infective germs reach the peritoneum through the anatomically unchanged intestinal wall or the internal genitals in the female. If such a state of affairs could be accepted as possible, there is, of course, no way of obtaining any clinical demonstration of the fact, nor would it constitute any contradiction to an infection by contiguity, for minute abscesses of the liver or suppurating mesenteric glands may likewise fail to give rise to any clinical signs and only become evident in a carefully performed autopsy; and even here small primary foci, such as perforating intestinal diverticula and slight circumscribed inflammatory processes in the female genital tract, may be easily overlooked. Thus in children an apparently primary peritoneal inflammation has been traced to a microscopic endometritis or salpingitis of streptococcic origin.

The diagnosis of a hematogenous or idiopathic peritonitis must therefore be accepted with considerable scepticism, even if an autopsy fails immediately to reveal the origin of the process. An account of two cases recently published by Oppenheimer in the *Zeitschrift für Chirurgie*, Vol. 83, No. 5, affords a good demonstration of this fact. In one an operation was undertaken for the removal of a pyloric tumor. The patient made a good recovery, but five weeks later developed, without apparent cause, evidences of a severe general infection, which rapidly went on to a fatal issue. The autopsy disclosed a seropurulent gastritis and a general peritonitis, although the former could not be definitely demonstrated until a microscopical examination had been made. It is probable that in this case infection of the peritoneum took place through the stomach wound, this having been incompletely healed or else subjected to traumatism from the food. In another instance a baby with an attack of general erysipelas which ended fatally showed the presence of a general peritonitis on autopsy. The presence of a layer of fibrin on the spleen led to a closer examination of this organ, which showed numerous circumscribed foci of streptococci near the surface, and these were surrounded by areas of necrosis. The kidneys and the thyroid contained similar foci as did the vessels, constituting a picture such as is often seen in fatal cases of erysipelas. The close relation of these splenic foci to the peritoneum is undoubtedly sufficient to account for the infection of the latter.

These cases show how small and easily overlooked pathological processes may lead to the production of a severe and even fatal purulent peritonitis. In every instance, therefore, in which no gross lesion can be found to account for the production of the latter, it would be a wise procedure to make a more extended microscopical examination of suspicious organs. Oppenheimer's communication serves to add further proof that the diagnosis of hematogenous or idiopathic peritonitis is probably not a true one and should not be accepted unless such minute or obscure sources of infection as those noted can be eliminated.

THE ETIOLOGY OF HEPATIC CIRRHOSIS.

Progress in our knowledge of the individual diseases has been marked in almost every instance by the close association of clinical observation with pathological anatomy and experimental investigation. Clinical observation may have pointed out the way in which experiments could be directed towards a solution of the etiology and pathogenesis of a given disease, and conversely experimental research has led to results which were capable of clinical application. Following along this line, the endeavor has been made to produce hepatic cirrhosis in animals by experimental means in order to gain an insight into the etiology of the process, but the results obtained thus far unfortunately do not permit us to draw any definite conclusions. Clinical observation suggested the fact that cirrhosis of the liver might perhaps be brought about experimentally in animals by the ingestion of alcohol. But this attempt failed, and it was only by the inhalation of this substance in rabbits that a pathological picture was produced similar to that which we associate with hepatic cirrhosis in the human subject. It was also thought possible that the gastric disorders which accompany chronic alcoholism might exert an influence in the development of a cirrhosis by producing deleterious disintegration products from food as the result of faulty digestion, and this led to the experiment of adding certain fatty acids to the ingested food. And here it was found that the administration of butyric and even of acetic acid was apparently instrumental in producing the lesion in question. It might also be expected that if we could apply in such experiments an agent which exerted an undoubted specific action on the liver cells, some more definite result would be obtained. A hepatotoxic immune serum apparently fills this requirement, but its use has not been followed by the hoped-for result. Of greater importance, particularly for clinical medicine, is a more complete knowledge of the rôle of the microorganisms and their toxins in the production of cirrhosis of the liver. The injection of staphylococci and tubercle bacilli has indeed in many instances been followed by the production of a lesion which presented all the microscopic evidences of cirrhosis.

It has been thought advisable to group cases of hepatic cirrhosis according to their clinical course and anatomical picture, but as a matter of fact we may have the same etiological basis in a most varied

series of anatomical pictures. An interesting study of this subject has lately been made by Jagic in Nothnagel's clinic (*Wiener klinische Wochenschrift,* No. 35, 1906) which is based on the clinical course and subsequent autopsy findings in a considerable number of cases. Taking up first the question of alcoholism as an etiological factor in the production of a cirrhosis, statistics are presented which apparently controvert the generally accepted notion regarding this matter; for among several hundred autopsies hepatic cirrhosis was found about as often in nonalcoholic as in alcoholic subjects. The writer is therefore inclined to support the contention of Klopstock and others, that alcohol does not furnish the direct cause, but rather a predisposition to the development of a cirrhosis.

Another class of cases to which Jagic calls attention includes those in which cirrhosis is present although the patient is not addicted to the use of alcohol, but where the symptoms due to tuberculous infection dominate the clinical picture. Animal experiments have demonstrated the possibility of producing a cirrhotic liver by infection with tubercle bacilli, and in view of this fact it seems reasonable to suppose that in the cases referred to by the writer the chronic tuberculous process was instrumental in producing the changes in the liver. It is quite likely that the primary cause of the cirrhotic process is a direct injury to the liver cells by a toxin derived from the tubercle bacilli.

There is no doubt that hepatic cirrhosis may be due to any one of a number of etiological factors. In addition to chronic alcoholism and tuberculosis, syphilis has been shown to be, and typhoid and cholera are claimed to be, causes in the production of this pathological lesion. The fact that tuberculosis may form the basis of a cirrhotic process in the liver constitutes an important addition to our knowledge of this disease and serves to explain many cases in which neither alcoholism nor syphilis could with certainty be regarded as an etiological factor.

The Bacterial Content of Milk and the Infantile Death Rate.

It is generally believed that the presence of bacteria in milk has a decided effect upon the health of young children. In fact, statistics bearing on this point would seem to show clearly enough that the infantile mortality rises with the presence of a large number of bacteria in milk and falls when these are comparatively few in number. The Health Board of Rochester, N. Y., has been particularly active for many years in its efforts to guard the health of the very young by carefully supervising the milk supply of the city. In the *Archives of Pediatrics* for September is an account by Dr. George W. Goler, Health Officer of Rochester, of the results of such efforts. The results of two five-year periods are considered, beginning with 1895. For the first four years of the first period, says Dr. Goler, milk and dirt were pasteurized together and the mixture was fed to children who were brought to the milk stations. In the last year of that period it was realized that it was better to keep dirt out of the milk and to sterilize the utensils. In the second period, beginning with 1900, over 5,000 samples of milk were examined annually for nutritive value, a larger number of stables and dairies supplying the city were included in the work of inspection, and the number of bacterial estimations of milk was gradually increased, until now more than one thousand are made each year. There were more deaths of children under five years in Rochester during the first period than in the second, notwithstanding an increase in population and the annexation of new territory to the city in the latter. During the second period the infantile death rate appeared to bear a close relation to the average number of bacteria per cubic centimeter found in the city milk supply. Dr. Goler and the Health Board of Rochester are advocates of, and carry into practice, cleanliness in the stable and dairy, and icing and sterilizing of the cans, and not of the milk, in handling the municipal supply. The system has certainly had excellent results. Perhaps, taking into consideration the evident intimate relation between bacteria in milk and infantile mortality, it might be advisable to establish if possible a uniform bacterial standard for milk. This has been suggested by many authorities, and, although there are immense difficulties in the way, in time a means may be found to bring about a satisfactory bacterial standard for milk.

The Follicles in the Appendix.

Considerable attention has been accorded to the follicles in the appendix, and it has been found that in some cases the number is comparatively small, while in others the entire mucous membrane is thickly studded with them. It has, therefore, become customary to regard the appendix as a lymphatic organ analogous to the tonsils and its inflammatory disturbances similar to the anginas. This has resulted in excluding the appendix when considering the diseases of the remainder of the intestinal tract and placing it in a class practically by itself. How far this is justified is discussed in a recent article by Hansemann, noted in the *Wiener klinische Wochenschrift,* No. 32, 1906. Follicles, no matter where situated, he holds, act as filters, whether they are in the bronchi, the lungs, or the intestines. Typhoid infection and tuberculosis become localized in the follicles, and it is also claimed, though this is less well known, that infectious diseases of various kinds, scarlet fever, diphtheria, influenza, pneumonia, sepsis, etc., are accompanied by a swelling of the follicles in the intestines, and that this must be looked upon as part of the disease process. This also applies to the appendix, although this part is not particularly predisposed to attack aside from mechanical causes. The follicles undoubtedly play an important rôle in the general pathological picture, but by no means represent the only factor. Hansemann believes, therefore, that the appendical inflammations should not be placed on the same level with ordinary tonsillitis, but considered as a different morbid process.

News of the Week.

The Harvey Society Lectures.—The second lecture in this course will be delivered at the New York Academy of Medicine on Saturday evening, November 3, at 8:30, by Prof. C. A. Herter. The subject of the lecture will be: "The Common Bacterial Infections of the Digestive Tract and the Intoxications Arising from Them."

Luncheons for School Children.—An excellent project has been put in operation in five of the public schools of the lower east side, whereby the

younger children are being supplied with luncheons each day. The luncheon consists of crackers and milk, and is distributed at 10:30 o'clock in the morning or at 2 o'clock in the afternoon. Each child is charged 1 cent for the meal. The Board of Education refused to furnish luncheons to pupils last April, after one of its committees had investigated a statement made by a society that 70,000 children were attending school without breakfast. The committee found that the statement was untrue, but that many children were not receiving proper nourishment.

A Committee to Investigate Human Heredity.—A committee of scientists and educators has been appointed by the Assistant Secretary of Agriculture for the purpose of investigating the practical application of the principles of heredity in relation to the welfare of the human race. The investigation is the outcome of work done in the Minnesota experiment station on the subject of heredity in plant and animal economics.

Illinois State Board of Public Charities.—At the meeting of this body, held October 18 and 19, 1906, the following committees were appointed: State Care, Including New Institutions, Miss Lathrop, Dr. George W. Webster, Dr. Evans, Dr. Churchill, and Mrs. Bourland. Medical Administration and Uniform Records, Internes: Dr. McAnally, Dr. Podstata, Dr. Wilhite, Dr. Davis. Hydrotherapy and Industrial Reeducation and Recreation: Dr. Podstata, Dr. McAnally, Dr. Carriel, Dr. Sanger. State Psychopathic Institute: Dr. Green, Dr. Podstata, Dr. W. E. Taylor. Improvement of Buildings and Grounds and Equipment: Dr. Emil G. Hirsch, Dr. Zimmerman, Dr. W. E. Taylor. Problem of the Feeble-Minded: Mrs. Bourland, Dr. C. B. Taylor. System of Charity Administration, Dr. Hirsch, Miss Lathrop, Dr. McAnally, Mrs. Bourland. Uniform Grades, Rules, Salaries and Nomenclature: Mr. Moulton, Dr. Athon, Dr. Podstata, Dr. W. E. Taylor. Local Business Administration: Dr. Hirsch, Dr. Green, Dr. W. E. Taylor. Special Committee on Joliet Prison: Dr. Hirsch, Dr. Webster, Mr. Zimmerman.

Patent Medicines in England.—That all the patent medicine fiends are not found in this country is shown by figures recently published regarding the sale of nostrums in England. The patent medicine traffic there amounts to nearly forty millions of packages, representing an outlay of nearly three millions of pounds sterling.

Salicylic Acid as a Food Preservative.—As a result of observations on a "poison squad" of twelve young Government clerks, Dr. Harvey W. Wiley, Chief Chemist of the Department of Agriculture, has announced that while salicylic acid is not as harmful as a food preservative as has been generally supposed, its use for this purpose is reprehensible. Its administration was found to be temporarily stimulating to the digestive organs, but in the course of time the processes of nutrition were interfered with, and a loss of weight was noted in the members of the squad.

Drug Consumption During the Japanese War.—If estimates recently published by *Red Cross Notes* are correct, the government physicians of Japan are far from being therapeutic nihilists. It is stated that quite early in the war upward of 100,000 ounces of quinine were demanded, and stocks of bismuth subnitrate and sodium salicylate were exhausted. Fifty thousand large cases of medical supplies were shipped from Japan at one time. The demands for adhesive plaster, gauze, cotton, and other surgical dressings were enormous, and supplies difficult to secure. Two million pills a day were supplied by the army's tablet and pill works in Tokio, Japan. The Government of Japan purchased all of the available stock of beechwood creosote, which was made into pills, and each soldier was required to take one a day to prevent dysentery. Each soldier carried a tin containing 90 pills and they were labeled "Russian Expedition Pills." The Government of Japan at one time purchased one hundred thousand pounds each of carbolic acid and corrosive sublimate.

Suit Against Surgeons.—Two Cincinnati surgeons are defendants in a suit for $10,000 damages entered by an individual who was engaged to furnish a certain amount of epidermis to be used in a case that required skin grafting. The plaintiff alleges that he agreed that a strip of skin one inch by six should be taken from his leg, but that while he was under the influence of an anesthetic skin was cut from both legs to the extent of forty-two square inches.

Examinations for Rabies at the Board of Health Laboratories.—In view of the fact that there has been a considerable amount of rabies in New York and vicinity during the past year, it is of interest to record the efficiency and promptness with which the Health Department staff is prepared to deal with suspected cases of the disease. In a recent instance several persons were bitten by a supposedly rabid dog at about ten A. M. in Harlem. By one o'clock one of the patients arrived at the rabies laboratory of the Health Department, foot of East 16th street. At once the police were notified to hold the dog, and a man was sent after its body. By four o'clock the body had reached the laboratory, and at half past four the diagnosis of rabies was positively established by means of the identification of Negri bodies in the cerebellum. By five o'clock the police had notified all the persons bitten of this fact, and advised that the Pasteur treatment be taken at the Health Department Station. Before the day was over one patient had already begun the treatment.

Diphtheria in Worcester, Mass.—A diphtheria epidemic of unusual severity is reported from Worcester, and 300 cases are said to have been recorded since August 1.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission will hold examinations November 17, 1906, for the following positions: Physician, Sixth Grade, State Hospitals and Institutions, $900 and maintenance; Superintendent of Nurses, Erie County Hospital, $1,200 and maintenance; Trained Nurse, State Institutions, $420 and maintenance. The Commission has been unable to secure a sufficient number of eligibles to fill the vacancies in the service in the positions of physicians and trained nurse, and qualified applicants have an excellent chance for appointment. The last day for filing applications for these positions is November 12. Full information and application forms for any of these examinations may be obtained by addressing Mr. Charles S. Fowler, Chief Examiner of the Commission, at Albany.

Gift to Somerset Hospital.—The Somerset Hospital of Somerville, N. J., has received the sum of $15,000 as an expression of the gratitude of a wealthy resident of Princeton for services rendered by the hospital physicians and attendants to a friend

who was injured in an automobile accident and taken to the institution.

Hospital Bequests.—By the will of the late Adolph Loeb, $500 was bequeathed to the Michael Reese Hospital, and $250 to the Alexian Brothers' Hospital.

Philadelphia Medical Club.—On October 19, a reception was tendered Drs. George McClellan and Edward Anthony Spitzka, recently elected professors of descriptive and applied anatomy in Jefferson Medical College.

Dr. Casey A. Wood has been elected Professor of Ophthalmology and head of the Ophthalmological Department of Northwestern University Medical School, with a service in Wesley Hospital.

Dr. Frank Allport was recently made Professor of Otology in the Northwestern University Medical School, a position which was vacated through the resignation of Dr. Henry Gradle.

Dr. Arthur R. Reynolds, who was formerly Health Commissioner of the city of Chicago, has resumed practice in that city.

Retirement of Dr. John C. Warren.—On October 16, the sixtieth anniversary of the first public administration of ether, Dr. John C. Warren, in addressing the medical men assembled in the Massachusetts General Hospital for the purpose of commemorating the first operation under ether, which was performed by Dr. John C. Warren, the grandfather of the speaker, announced his own retirement from the surgical staff of the institution, which he had served for thirty-five years.

Professor Pierre Janet of the Medical Faculty of Paris began last week, in Boston, a course of fifteen lectures on Hysteria. The lectures are open to all physicians and to teachers of psychology without charge. They are being given in the Administration Building of the new Harvard Medical School group at 8 o'clock on Mondays, Wednesdays, and Thursdays.

Resignation of Dr. Carlos F. MacDonald.—At a meeting of the faculty of the University and Bellevue Hospital Medical College held on October 8 the resignation of Dr. Carlos F. MacDonald as Professor of Mental Diseases and Mental Jurisprudence was accepted, and the Advisory Board recommended to the Council of the New York University that Dr. MacDonald be made Emeritus Professor of the same subjects.

Vermont State Medical Society.—At the ninety-third annual meeting, held in Barre, Vt., on October 12, officers were elected as follows: *President,* Dr. D. C. Hawley of Burlington; *Vice-President,* Dr. C. W. Strobel of Rutland; *Secretary,* Dr. George H. Goreham of Bellows Falls; *Treasurer,* Dr. P. H. Stone of Burlington; *Auditor,* Dr. J. H. Blodgett of Saxton's River.

Officers of the Chicago Surgical Society.—At the recent annual meeting of this society the following officers were elected for the year 1906-7: *President,* Dr. D. W. Graham; *Vice-President,* Dr. Jacob Frank; *Secretary,* Dr. William Hessert; *Treasurer,* Dr. F. A. Besley; *Council,* Drs. E. W. Andrews, D. A. K. Steele, and A. E. Halstead; *Representative in the Council of the Chicago Medical Society,* Dr. S. C. Plummer.

Officers of Chicago Gynecological Society.—The annual meeting of this society was recently held, at which the following officers were elected for the ensuing year: *President,* Dr. J. C. Hoag; *First Vice-President,* Dr. Joseph B. De Lee; *Second Vice-President,* Dr. Rudolph W. Holmes; *Secretary,* Dr. Henry F. Lewis; *Treasurer,* Dr. Charles B. Reed; *Pathologist,* Dr. George Schmauch; *Editor,* Dr. Frank W. Lynch.

Sanitary Officers of New York State.—The sixth annual conference of this body was held in Syracuse on October 24, 25 and 26, under the direction of State Commissioner of Health Eugene H. Porter. Among the subjects discussed were sanitation and politics, sanitation at summer resorts, public water supplies and their purification, meat inspection, the value of the sanatoriums in the anti-tuberculosis movement, etc. In his address Dr. Porter pointed out the necessity for more liberal appropriations for the work of the department. Pennsylvania last year appropriated $350,000 for its health department, whereas in this State last winter only $75,000 was allowed for this purpose.

The National Association for the Study of Epilepsy and the Care and Treatment of Epileptics.—The sixth annual meeting of this association will be held in the New Haven Medical Association Rooms, 962 Chapel street, New Haven, Conn., at half past two P. M., November 8, 1906. The president is Dr. Max Mailhouse of New Haven, and the Secretary, Dr. J. W. Wherry of Davisville, N. Y.

Mississippi Valley Medical Association.—The thirty-second annual meeting of the Mississippi Valley Medical Association will be held at Hot Springs, Ark., on November 6, 7, and 8, under the presidency of Dr. J. H. Carstens of Detroit. The secretary is Dr. Henry Enos Tuley of Louisville, Ky. Dr. Frank P. Norbury will deliver the address in Medicine, taking as his subject "Clinical Psychology." The address in Surgery will be delivered by Dr. Florus F. Lawrence, his subject being "Surgical Principles and Theories."

Stafford County (N. H.) District Medical Society.—This body held its ninety-ninth annual meeting at Dover on October 17, and elected the following as officers: *President,* Dr. P. H. Greeley of Farmington; *Vice-President,* Dr. L. L. Stokes of Rochester; *Secretary,* Dr. L. W. Flanders of Dover; *Treasurer,* Dr. A. N. Smith of Dover.

Cheshire County (N. H.) Medical Association.—At the annual meeting of the society held on October 9 at Keene the following officers were elected: *President,* Dr. John D. Proctor; *Vice-President,* Dr. A. H. Childs of Dublin; *Secretary, and Treasurer,* Dr. E. G. Dearborn of Keene.

New York and New England Association of Railway Surgeons.—This society will hold its sixteenth annual meeting at the New York Academy of Medicine Wednesday and Thursday, November 14 and 15, 1906. The president is Dr. J. P. Creveling of Auburn, N. Y., and the secretary, Dr. Geo. Chaffee, 338 47th street, Brooklyn, N. Y.

In Memoriam.—Dr. A. Martin Pierce of New Bedford, Massachusetts, died November sixth, nineteen hundred and five. The memory of the skillful and beloved physician and faithful friend is cherished, not by his friends and patients only, but by the whole community in which he lived.

Obituary Notes.—Dr. BERNHARDT FINCKE of Brooklyn died on October 21. He was born in Germany eighty-five years ago, and had practised medicine in Brooklyn for fifty years. He was a member of the American Institute of Homeopathy, and at one time was President of the International Hahnemannian Union.

Dr. Charles P. Russell of Utica died of pneumonia on October 26 at the age of fifty-eight years. Dr. Russell was a native of Utica, and had specialized in diseases of the skin. His medical education was gained in Ann Arbor Medical College, Bellevue Hospital Medical College, and in Vienna and Edinburgh.

Dr. T. S. Foster of Laconia, N. H., died on October 25 at the age of seventy-eight years. He was born in Richmond, Me., and was graduated from Bowdoin College in 1862. After serving as a surgeon in the Civil War he began practice in Laconia in 1865, and continued in active work until two years ago.

Dr. William Fuqua of Jonesville, Tenn., died on October 20 at the age of seventy-eight years. He was graduated from the Richmond Medical College and served in the Confederate Army as surgeon.

Dr. W. E. Todd of Jackson, Miss., died on October 17 at the age of forty-nine years. He was graduated from the Bellevue Hospital Medical College in 1877, and practised for some years at Leota Landing and other places along the river. In 1887 he removed to Jackson and had practised there since that time.

Dr. C. Weschke of New Ulm, Minn., died on October 12 at the age of seventy-five years. He received his medical education in Germany, but came to this country about fifty years ago. He was one of the earliest settlers in New Ulm, and had held many official positions in the city.

Dr. William H. Carothers of Melrose, Mass., died of pulmonary hemorrhage on October 23 at the age of fifty-two years. He was a graduate of Jefferson Medical College, and had practised in Melrose for about eight years.

Correspondence.

HOSPITAL REFORM.

To the Editor of the Medical Record:

Sir:—Dr. Stark's suggestions as to hospital reform are good and timely, but perhaps do not go far enough. I would suggest that all paying patients be allowed to choose their own doctor, and that the hospital be responsible only for care of operating room and nursing. His proposal to open the doors to a selected few amounts, in fact, to a widening of the door, not to an open door.

For the last ten years I have held the position of gynecologist to the Nathan Littauer Hospital, of Gloversville, an institution of about forty-two beds, of which eighteen are in private rooms. There is a medical and surgical staff, the members of which are obligated to attend, free of charge, any person too poor to pay for hospital or medical care, but all patients who pay the hospital for board and nursing, whether in ward or private room, may choose their own physician, and make their own terms with him. The door is wide open; there is no distinction of creed or school; any lawful physician or surgeon may practise or operate in the hospital.

What is the result? Just what it is in private practice; some get more, others less, but all start on an equal footing, with the exception that the members of the staff have the benefit of the prestige that goes with a hospital appointment. The hospital takes its proper place, *i. e.* a hotel for the sick man or woman who can pay, and a haven of refuge for the one who cannot. It is not a medical trust, like some of the hospitals in the larger cities, where it requires a pull to get on the staff, and a pull to stay on. There are plenty of hospitals for the sick poor, but what are needed are hospitals for the sick who are in moderate or very moderate circumstances. The rich can go to private sanatoriums, but the self-respecting workingman, mechanic, clerk, or salaried employee should have a place which will come within his means, and at the same time have the liberty—yes, the right—to retain his family physician; and it is only fair that that physician should not be obliged to lose a patient when he advises him that he needs hospital care.

William C. Wood, M.D.

Gloversville, N. Y.

THE CHOICE OF COW'S MILK.

To the Editor of the Medical Record:

Sir:—The writer has had a somewhat unusual, if not unique, experience in the experimental breeding of dairy cattle of various breeds, and has made a very extended study of the relation of butter fat to solids not fat in milk. He, therefore, feels justified in pointing out one error of statement in the article of Dr. J. Allen Gilbert, on the "Choice of Cow's Milk," in the Medical Record of October 27. As a matter of fact, there is very little difference in the relative proportions of butter fat to solids not fat in the milk of individual cases of the cows of the several breeds. Where there is a notable difference it is a matter rather of individuality of cow than of breeds. A cow's milk that is poor in milk solids simply has a larger proportion of water. The cow has a larger vascular system and more bulky udder. Other things being equal, the more water a cow has in her general system the more economic will be her vital processes; but under pasturing conditions involving much locomotory work, as is usually the case in American pastures, a very large milk flow and the accompanying need of the carrying around of the larger burden of water, is an uneconomic condition.

There can be no question that a diluted milk is of easier digestion than a rich milk, but I have never had the slightest trouble in feeding very rich milks to either calves or babies if it were only diluted sufficiently, and provision made against hardness of congestion by admixture with cereal gruels.

It is not true that under correct treatment Jersey cattle are more subject to tuberculosis than other cattle. On the Island of Jersey the disease is unknown among cattle—a fact in great measure due to the amount of open-air life possible for dairy stock there. Nor are they so much subject to tuberculosis under favorable climatic conditions of environment as are the less nervous but more hardy breeds. They do not, as a breed, have as strong a heart action as some cattle, and hence need more care as to ventilation than some of the more active breeds; but, in the milder regions of the United States, where much out-of-door life is a possibility, or after several generations of adaptation to pasturing life and longer stabling conditions of the north, they become as resistant to germ invasion as other cattle. Other things being equal, the phlegmatic cow succumbs to tuberculosis more easily than the highly-bred, nervous cow. It is not true that the cow that will give the most milk is the most healthful cow. The reverse is the fact. Very large production is surely followed by effects due to weakening of digestion and other functions. Galactorrhea is a disease of cows more frequently seen than in women. The less milk a cow gives the more healthy she will be if fed correctly. The correct ideal in connection with a healthful milk is to be found in the line of moderation as to quality of solids content and as to bulk of flow, and as to adaptation of type of cow to special environment. The Holland cow is the cow for Holland, and for certain flat and rich lands elsewhere. The Jersey is the cow for our southern States, and certain of her types giving a large flow of moderate richness are economically desirable for most of our northern States. The dairy type of the Ayrshire is also all right for rough northern pastures, but there are more good Jerseys suited to a combined economic requirement on the part of the farmer and the consumer than can be found in any other breed. There is a tremendous variation of type and individuality in every breed, and the milk dealer who waters his milk, or sells skim milk, is not the social monster he is represented to be. Diluted milk is a safe food. Nevertheless, young calves and babies need a large proportion of fat in their diet to create force.

East Orange, N. J.

OUR LONDON LETTER.

(From Our Special Correspondent.)

TROPICAL SCHOOL—INTERRELATIONSHIP OF DISEASE—"DRUG CURES" FOR INEBRIATES—INDIAN DRUGS AND PHARMACY—OBITUARY.

London, October 12, 1906.

The London School of Tropical Medicine is now in full work. The session began with an opening address by Col. Kenneth Macleod, honorary physician to the King. Since the school was established, seven years ago, over 600 students have attended, including some who intended to devote themselves to practice at home; the others in order to qualify themselves for the Colonial, Indian and Foreign services. Col. Macleod remarked that as tropical countries have peculiar flora and fauna of which no teaching of botany and zoology and no study of the planets and animals of temperate regions can supply a knowledge, so there are

in the tropics manifestations and modifications of diseases as to which the medical schools of this country afford but little information. This analogy, he continued, was by no means strained, for the pathology of to-day was largely concerned with botany and zoology, a fact freely recognized in this school. Through the liberality of the Colonies protozoology and helminthology had been added to the curriculum. The study of vegetable microbes was included in that of the diseases with which they are associated; but, to complete the teaching of parasitology there was another subject which ought to be systematically developed, viz., pathological entomology. Insects, especially blood-suckers, conveyed infective diseases and harbored the transmission of germs. Knowledge of this subject needed to be taught and extended. Recent researches indicated that leprosy is spread by insect agency and cholera; typhoid and plague were probably so transmitted, though additional light on these and cognate subjects was needed. Physiologists and pathologists had been accused of callousness, selfishness, and cruelty in subjecting animals to experiment, but in the investigation of tropical diseases men had themselves in many instances risked health and life. The course of yellow fever was discovered through such volunteers. The study of tropical diseases had greatly contributed to the marvelous progress of the last quarter of a century. During that period there was hardly a subject that had not been illuminated. In malaria, cholera, plague, leprosy, and other diseases, special causes had been demonstrated and indications for prevention and treatment obtained. But, as the circle of knowledge widened, the horizon of ignorance seemed to extend, and much work, such as this school could aid and foster, remained to be accomplished.

The Medical Society of London opened its 134th session on Monday, when Mr. Ballance delivered his inaugural address, taking as subject, "Then and Now in Surgery." His predecessor in the presidency had spoken of the great changes which had taken place within his own experience in the science and practice of medicine. So our new president thought well to give as a corollary an account of the development of surgery in his time. But he also included a sketch of what had gone before, mentioning in that some of the more interesting phases of surgical history. He referred to the question of vivisection, and noted the opposition of Celsus, who said enough could be learned from gladiators, soldiers, and others, who had been wounded. He pointed out that in all ages search after truth of all kinds had met with obstruction, related examples of valuable additions to our knowledge, and thought it might be considered useless before that audience to refer to the necessity of experimenting on animals; said he felt it necessary to say frankly what he held to be true on the subject.

Mr. C. B. Keetley, on Wednesday, addressed the Post-Graduate students at the West London Hospital, of which he is the senior surgeon, on "The Interrelationship of Disease." In considering the subject he said the first essential was to grasp the all-prevailing influence of the microbe, for all disease might be due to it. Even when a man was killed by dissipation or drink, or the consequences of an injury, probably in nine cases out of ten the trouble would not have been fatal but for the intervention of the microbe. Next, they should remember that all microbes have an ancestry. Practically, people got all their diseases directly or indirectly from one another, and it was time to cease blinding themselves by limiting the term infectious to a small class of diseases. A rapid gastric ulcer was as much infectious as any fever; all prophylaxis lay mainly in the sterilization of food; the limitation of intercourse, general cleanliness, and special aseptic and antiseptic treatment, adopted stringently and at the right time against special risks. In the course of his lecture Mr. Keetley also pointed out the economic injuries inflicted by disease and immorality.. A single child affected with tuberculosis was a great strain on its parents or on the philanthropic. Even a great hospital like this was greatly weighed down by numerous cases of the kind; so no wonder parents and families were seriously affected as to their pecuniary resources and social position. Tubercle tended to impoverish and degrade a family, and so led to drink and physical degeneracy. In this matter he had for many years held the views expressed lately by Sir F. Treves and Sir V. Horsley, and he rejoiced that they had spoken out. Publicans were out of all due proportion the victims of tuberculous and other diseases.

At the Society for the Study of Inebriety, on Tuesday, Dr. Mary L. Gordon gave an address on the "Drug Treatment." She said these "drug cures" came to this country between 1892 and 1898, when the Inebriate Acts began to gather patients into retreats. It could not be believed that four weeks would be long enough to transform drink-sodden victims into sober, healthy persons. The chief ingredient of most of the "cures" was strychnine, which was becoming a popular drug, some patients actually regarding it as a substitute for alcohol. The late Dr. Anstie had noticed that this drug occasionally produced symptoms closely allied to some of those due to alcoholic intoxication. Capsicum was also used in these cases, and was one of the most insidiously dangerous of all the drugs commonly employed. The scientific use of drugs was not to be condemned in any disease, but every case should be dealt with according to its symptoms and pathology. In these days so-called drug "treatments" for any derangement were "not good enough."

Last week Sir George Watt, Reporter on Economic Products to the Indian Government, delivered an interesting lecture at the Pharmaceutical Society on the Pharmacy of India, native and European. He remarked that in all the important Indian towns there were chemists' shops, mostly owned by Europeans, worked on European lines by Europeans, and where prescribing, as well as dispensing, went on. Nearly all these chemists were also manufacturers of aerated waters. The native chemist was more a herbalist than chemist, and often combined the trade of a grocer. He sat in a den six or eight feet square and dispensed from jars, bags, boxes, and bottles, medicines, charms, spices, and even poisons, about which questions were never asked, and he knew more about the sufferings and crimes of the villagers than anyone else. He collected plants and herbs from the jungles, or bought them from residents in the jungle. He was an attractive personality from the halo of mystery surrounding him and his knowledge, which was hereditary, his experience being handed down from father to son. Considering the small number of qualified doctors the Indian universities turned out in proportion to the population, it had been calculated that it would take 200 years before Western medical skill could reach the remotest parts of the Empire, and, therefore, he recommended the study of the indigenous drugs and preparations, and the dissemination of the knowledge of their uses. Out of some 1,500 drugs used by the natives, only about a score had been thoroughly investigated. In many instances the knowledge of the natives was of a high order. For example, effectual methods of sterilizing milk had been adopted in India for over 2,000 years. It was the practice in India to boil all milk for two or three hours consecutively, or to boil it repeatedly for shorter periods, never letting it get quite cold. In this way toxic germs were destroyed, and it would be better for Europeans to follow this plan, instead of striving after fresh cream and butter, which, if more palatable, were infinitely more dangerous. The manufacture of condensed, and of desiccated milk, had been practised in India from time immemorial. Cream had to undergo a special fermentation before it could be churned into butter, which was clarified before being used under the name of ghee as a substitute for dripping, and not to spread on bread after European fashion. About thirteen and a half millions sterling was realized in India by the manufacture of ghee, which was mentioned in most of the Hindoo classics. If carefully enclosed in skins, when hot, it would keep for hundreds of years. Mixed with various perfumes, it was the chief ingredient in Eastern unguents and ointments. So highly was it prized that large stocks of it were kept by rich people for their own use and for distribution among their poorer brethren.

It is refreshing to hear of a public body appreciating medical services, so I chronicle the conduct of the visiting committee of the Bucks County Lunatic Asylum, which is inviting subscriptions to a testimonial to mark the public sense of Dr. John Humphry, who, before the close of 1906, will have completed fifty years of service as medical superintendent. His duties are said to "have been performed to the entire satisfaction of the committee, to the advantage of the county, and with uniform kindness and consideration for the unfortunate patients under his charge."

At an inquest the other day it was shown that a poor woman died soon after taking two tablets of "Burkard's Vegetable Compound." A sample packet had been pushed under her door, with the usual assertion that this quack medicine would cure all sorts of maladies, and if one tablet did not relieve another should be taken. The medical evidence was that the woman died from the effects of the tablets. As the packet had the word "poison" on it, the jury seem to have thought that warning enough, and returned a verdict of misadventure. The case is surely one for the criminal law, but so far no steps have been taken to punish the distributors of this "poison."

Dr. James Finlayson, M.D., LL.D., Sc., of Glasgow, physician to the Infirmary, died on Tuesday of apoplexy. He qualified in 1867, and has long held a conspicuous position in medical practice and literature. You will know his "clinical manual." He wrote the Life of Peter Lowe, who founded the Glasgow Faculty of Physicians and Surgeons; also the Life of Dr. R. Watt, the author of the *Bibliotheca*

Britannica. Among other contributions, one on Galen, and many excellent papers of a more strictly professional kind to both the societies and the journals.

Dr. H. W. Syers, physician to the Great Northern Central Hospital, died on Wednesday, at the age of fifty-four, from bloodpoisoning contracted in practice. He was a Cambridge graduate, M.A. 1878, M.D. 1883. He was a member of several of the societies to which he contributed, as well as to the journals. He wrote the "Theory and Practice of Medicine," 1891, and when resident at the Westminster Hospital edited its "Statistical Reports," 1885-6-7. He was the translator of "Morat's Physiology of the Nervous System," and some other works.

Dr. E. Long, J.P. of Dublin, has died at the age of eighty-three. He was the originator of certain preparations of ergot, and long connected with pharmaceutical work. He took the Dublin Hall diploma in 1850, M.R.C.S. 1851. Had been retired many years.

The deaths are announced of the following army medical officers: Lieut. Col. Crombie, aged sixty, late of the Indian service, which he entered in 1872. He had been professor in the Calcutta University, served in Burma 1875, Bengal from 1875, retired in 1898. Subsequently he lectured on tropical diseases at the Middlesex Hospital and at the London Tropical School. He contributed papers on these diseases. He was a member of the Indian Medical Board. Lieut. Col. E. Burroughs, aged fifty-six, entered the Indian service 1875, served in the Afghan war 1878-80, taking part in Maiwand Kandabar, etc., being mentioned in despatches, and receiving medal and clasp. Lieut. Col. F. A. Harris, aged fifty, joined the Royal Army service in 1881, served in Egypt 1882, and received the Khedive's bronze star; then in the S. A. war, for which he held the Queen's medal and four clasps; retired in 1903. Surgeon-General Wm. Williamson, aged eighty-six, served from 1844; retired in 1879. Captain A. T. Pilkington died in India, aged thirty.

CONGRESS OF ALIENISTS AND NEUROLOGISTS—THE BLOOD OF THE INSANE—SENILITY—RESPONSIBILITY IN HYSTERIA—ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE—OTHER CONGRESSES.

PARIS, October 3, 1906.

DURING the first week of August the Sixteenth Congress of French-Speaking Alienists and Neurologists was held in Lille under the presidency of Professor Grasset of Montpellier. Three principal topics were discussed. The first, presented by M. Maurice Dide of Rennes was the study of the blood in the insane considered in regard to cytology, bacteriology, and from the experimental standpoint. The paper was a very long one, comprising an extensive study of the literature, and also many personal observations. The speaker's conclusions were as follows: Taken as a whole, the blood of the insane, in regard to its color, density, coagulation, alkalinity, retraction of the clot, and percentage of urea and mineral constituents, presents no noteworthy features. In mental diseases of a toxic or infectious nature blood cultures are often positive, without yielding any germs that can be considered as being specific. The bacteria obtained from the blood during the afebrile periods may be considered as being saprophytes in the sense that they are not naturally injurious to animals, and that they do not betray their existence by any clinical symptom. These organisms are of considerable importance, because their virulence may be augmented, and they may become important factors in the production of pathological phenomena. Taking up the effect of infections on the psychopathic states it may be said that in general it is salutary, but it is necessary to distinguish carefully between the acute stage of the disease and the period of convalescence. The febrile disorders during their acme exercise a sedative influence on states of agitation, which is due to the inhibition of the nervous centers caused by the toxins abruptly set at liberty. During the period of convalescence, on the contrary, there occurs a state of organic repair following the victorious reaction of the body, which may be very useful to the mentally-disordered patient. If a rational plan of treatment of insanity is ever evolved it will take into consideration these facts.

The second contribution, on the senile brain, was presented by M. A. Léri of Paris. The speaker first showed, by reference to his personal observations, case histories, and numerous original anatomical drawings, what he meant by this term, both from the psychiatrical and neurological standpoints. Old age and senility are not synonymous; old age is the last period of life, and a conventional time, say sixty years, may be set for its beginning. Senility is a pathological state which is not a necessary concomitant of age, may commence much later or much earlier than old age, and may be observed to a very variable degree in the different organs of the same individual, and even in the different parts of the same organ. It is, therefore, justifiable to speak of delayed senility, of premature senility, of general senility, and of localized senility. There is no senile organ, and especially no senile brain, without lesions; these may be macroscopic, or simply microscopic. They consist in atrophy, simple or degenerative, of the parenchymatous elements, in more or less extreme proliferation of the interstitial tissues, and in sclerotic changes in the vessels. These three varieties of the lesion appear to depend, not one on the other, but all three on alterations in the blood, and the sum total of the intoxications, exogenous and endogenous, acquired throughout the entire existence of the individual, and often aggravated at an advanced age, in consequence of certain organic defects. The clinical signs, for the most part, are those of cerebral arteriosclerosis, including vertigo, transitory aphasia, hemiplegia or paraplegia, hesitating gait, spasmodic laughter or weeping, sometimes even epilepsy. As far as the mental state of old persons is concerned, all stages of transition between perfect preservation of intelligence and senile dementia may be observed. The senile weakening of intelligence and simple dementia apparently must be explained by atrophy and degeneration of the cerebral cells and nerve fibers.

The third contribution, which was presented by M. Raoul Leroy of Ville-Evard, dealt with the responsibility of hysterical patients. The speaker considered the subject from the practical standpoint, and divided his essay into two principal parts; the first included a résumé of the criminal or immoral acts of such patients, and the second was devoted to a discussion of their responsibility for their actions. The author took up in order the different types of hysterical mania: lying, theft, homicide, assaults, acid throwing, poisoning, suicide, incendiarism, etc. He concluded that the responsibility varied not only in different individuals, but also in the same patient, according to the circumstances. The first thing to be considered was the patient himself, then the act itself, together with the circumstances which preceded it, accompanied it, or followed it. The conclusion seemed justified that, taking everything into consideration, responsibility was rare among the hysterical.

The next congress will take place in 1907 in Geneva and Lausanne under the presidency of Professor Prévost of Geneva; the subjects to be discussed are: in psychiatry, periodical psychoses; in neurology, the definition and nature of hysteria, and in forensic medicine, medicolegal experts.

The annual congress of the French Association for the Advancement of Science was held at Lyon during the first week of August under the presidency of Professor Lippmann. Professor J. Teisser, who presided over the medical section, in his opening address made a strong appeal to medical students to cultivate habits of close observation. Two very important questions were considered by this section. The first was the actual status of the experimental study of syphilis, and was discussed by M. Joseph Nicolas of Lyon. The corollary to this question was presented by M. A. Manquat of Nice, who spoke on the prophylaxis of syphilis and venereal diseases in its relation to prostitution.

The second question, relating to antituberculous immunization, was discussed by Professor Rappin of Nantes, and M. Fernand Arloing, chief of the bacteriological institute of Lyon. The former insisted strongly on the possibility of securing immunity by antituberculous vaccination, while Arloing presented the results obtained by antitoxic serum therapy.

Among the other interesting matters which were dealt with by the Congressists was the sterilization of drinking waters by ozone, and a discussion on the theory of congenital criminals. The Lyon school opposes the doctrines of the Turin school as presented by Lombroso, and affirms that congenital criminals do not exist. Certain individuals, according to this view, do not resist the temptations of their environment, and are more predisposed than others to become criminals.

The next session of the congress will be held at Reims in 1907 under the presidency of Professor Henrot.

Among the other congresses to be held shortly it is interesting to note the following: The XIX. Congress of the French Surgical Association will be held at Paris from the first to the sixth of October, under the presidency of M. Monprofit. The principal topics to be discussed are the surgery of the large nerve trunks, ectopy of the testicle and its complications, and the means of operative access to the thorax.

At Marseilles, from October 7 to 13, the National Congress of Hygiene and Public Health will be held. The object of this congress is to encourage the dissemination of popular knowledge in sanitary matters, and the application of the methods and principles demanded by modern science. Later in the month the first International Con-

gress of Alimentary Hygiene, of which M. H. Ricard is president, will be held under the patronage of the president of the Republic. Finally, the Congress of Urology will be held early in October in Paris, under the direction of Professor Guyon. The principal topic will be the etiology and treatment of hydronephrosis.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA MEDICAL SOCIETY—TREMATODE INFECTION—CHOLERA OUTBREAKS—FAILURE OF THE CHOLERA SERUM—THE PLAGUE—BERIBERI—TYPHOID FEVER.

MANILA, P. I., September 19, 1906.

MONDAY evening, September 3, in the library of the Bureau of Science, the Manila Medical Society held its first meeting since the recess which was taken during the hot season. Dr. W. E. Musgrave, pathologist, read a paper upon "Trematode Infection in Man in the Philippine Islands." Dr. Musgrave has already observed thirty-seven cases of *Paragonimus westermanii* infection, and believes it is much more common in the Philippine Islands than has heretofore been thought to have been the case. The majority of the cases were observed at autopsy, it being rather the exception that a diagnosis was made during life. The number of times that he has encountered this disease at autopsies of cases, which had been diagnosed as tubercle of the lungs, leads him to infer that many of the deaths that have heretofore been reported as due to tuberculosis, may in reality have been caused by the lesions produced by this trematode. A noteworthy feature about the cases was that in a number of instances the trematodes were not confined to the lungs, but were found in various organs of the body, and particularly in the brain. He said that, upon making sections of the lungs, a large number of burrows were usually found to be scattered throughout the organ. He said that in the tunnels a material, which is similar to that of the sputum found in the living cases, is encountered. The walls between the burrows frequently break down, thus making large cavities. Owing to the fact that this disease has only recently been observed in the Philippines, and most of those present at the meeting not having seen any cases, there were not many persons present who were in position to discuss the paper.

During the early part of the month cholera was reported near Camp Vickars, Mindanao, among the Moros. About September 9 the disease was reported to be present in Dumangas, in the province of Iloilo. The outbreak of cholera in these two widely-separated places occasioned considerable surprise. The outbreak near Camp Vickars occurred about fifteen miles from the sea coast. In view of the fact that the Moros, ordinarily, are not likely to come in contact with other nationalities, and since they do not trade with Luzon, and scarcely ever visit it, it is not understood how the infection could have started among them. The outbreak at Dumangas, in the province of Iloilo, was equally puzzling, because, so far as could be learned, it occurred among persons who had not been away from Dumangas for several weeks preceding, and they were of a class that are considered to be too poor to purchase food stuffs which are likely to be imported. The town of Dumangas, itself, is in the interior, and has no direct communication with the island of Luzon, the latter island being the only one known to have been infected up to the time of this outbreak. It may be possible, later on, to trace the source of this infection, but at the present time the belief, which has been quite common among a number of medical men, that cholera is indigenous in the Philippines, certainly seems to have gathered additional force by the two outbreaks referred to. The spread of the cholera from Dumangas to Buena Vista, to the port of Iloilo and its various barrios, has not been difficult to trace. So far there has been a total of 108 deaths reported in Iloilo province; the number of cases is not positively known. In the Moro province there have been nine cases.

The outbreak of the disease in these two provinces is particularly discouraging at the present time, because it was hoped that cholera could be entirely eradicated from the Philippines in the near future. This hope was very much strengthened by the rapid decrease in the number of cholera cases which occurred in Manila and the island of Luzon, generally. For the first two weeks of September there were 46 cases with 40 deaths in Manila, and for the provinces 334 cases with 301 deaths, as against the last two weeks of August with 74 cases and 67 deaths for Manila, and 576 cases with 499 deaths in the provinces.

Dr. Denier, bacteriologist of the Pasteur Institute of Saigon, who has been in Manila for the purpose of testing the value of his curative serum in cases of cholera, returned to Saigon. He expressed himself as not feeling very much encouraged over the results that he obtained with his serum. While the serum which he made from live cholera organisms gave better results than that which he made from the dead organisms, his mortality record, even with the former, was not particularly favorable. Deducting those cases which actually arrived at the cholera hospital in a moribund condition, he treated in all seventeen cases, of which twelve died, which gives a mortality of about 74 per cent., which is not as good as the results obtained by the ordinary medical treatment at this stage of the epidemic.

Owing to the great improvement in the plague situation at Amoy, the strict quarantine regulations which have been enforced by the Philippines against that port have been considerably modified, and the same will go into effect October first. Vessels from Amoy will now only be required to stop at the quarantine station at port of entry in the Philippines, where the necessary disinfection can usually be accomplished in a few hours, after which the vessels are permitted to proceed without further detention. Manila still remains free from plague, no cases having been reported since April 20, 1906. For this reason the most rigid precautions are being taken to prevent its reintroduction into the islands.

The small epidemic of beriberi which broke out among the lepers at the Culion Leper Colony has apparently been arrested. If diet has no effect upon this disease it is, at least, a remarkable coincidence that, after a liberal amount of nitrogen was introduced into the ration, the number of cases immediately became less.

An outbreak of typhoid fever has been reported among the United States troops which are stationed on the island of Gimras. Spanish physicians who have spent most of their lives here, claim that even during Spanish occupation the island of Gimras was noted for its unhealthful character, and that frequent outbreaks of fever occurred, the symptoms of which resembled enteric fever.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 18, 1906.

Fibroma of the Ileum Causing Bowel Obstruction.—J. W. Dewis reports the case of a woman of 64 years who for ten years had had more or less constipation with, during the later portion of the time, vomiting, ravenous appetite, and a bloated feeling. On one occasion, after a very hearty meal, symptoms of acute intestinal obstruction came on, and then subsided, so that it seemed as if the obstruction, whatever it was, had disappeared. The symptoms returned suddenly, however, and she died from shock, no operation having been done. Autopsy showed in the region of the ileocecal valve an intussusception about two inches long, with a round, movable body attached to the lower end. This mass, including an inch or two of ileum above and below the invaginated portion, was removed. The intussusception was easily reduced, and there was no noticeable edema of the bowel. Growing from the wall into the lumen of the bowel, and about four inches above the ileocecal valve was a small oval tumor, dark-brown red in color, and slightly mottled. On section it was dull and fibrous, the center a dull white, with fan-like radiations. Examination proved it to be a small fibroma springing from the submucous layer. The author collates the previously reported cases of benign intestinal tumors, and makes a careful study of them, which cannot be reproduced here.

The Bier Treatment of Infectious and Septic Wounds of the Extremities.—E. A. Codman thus describes the plan followed by him in dispensary practice. When an old patient (one seen the day before) arrives in the morning, his dressing is taken down, the wound is examined, and its condition recorded. A rubber strap two inches wide, and provided with a buckle, is applied about his arm or leg well above the lesion. This is drawn as tight as possible without stopping the pulse. The wound is covered with moist bichloride gauze, and the patient sits down and waits an hour. The part is looked at from time to time, to be sure that the circulation is not too greatly checked. At the end of the hour a moist dressing and splint are applied. The wound is not, as a rule, packed or drained. The same routine is followed each day. After the first few minutes the pain is inconsiderable, and, if pain has been present before, it is usually relieved. Patients not infrequently bring a book or a newspaper to read during the hour. While the tourniquet is on the wound secretes more profusely, usually serum with particles of pus and necrotic tissue. In several cases after the

treatment it was noticed that adjacent pockets had broken into the main one, or on the surface. If slough has presented at the surface of the wound it has been picked out, but, on the whole, delving and probing in the wound have been discouraged. Codman believes that this plan of treatment assists nature in building a barrier about the necrotic focus, and when this barrier has been once formed, assists in removing the focus.

New York Medical Journal, October 20, 1906.

Fatal Scopolamine Poisoning.—The history of the case is given by G. W. Ely. The patient was a married woman of twenty-nine years, with carcinoma of the larynx. Early in the morning she was given a hypodermic injection of one-eighth grain of morphine and one-hundredth grain of scopolamine, the intention being to repeat the doses after the usual manner of administration. Contrary to instructions, she got out of bed, dressed, and went out of doors, returning in half an hour, and lying down. Soon it was noted that she was sleeping, the breathing being stertorous and the face cyanotic. The hospital surgeon was called, and found the patient in coma. The pupils were moderately dilated, but reacted to light; the tongue, mouth, and pharynx were extremely dry; the surface of the body was also dry and pale. The superficial reflexes were abolished. The pulse and respirations were practically normal, but soon the respirations became shallow and less frequent. This latter condition was progressive in spite of the treatment, and the patient finally died from paralysis of respiration about two hours after the administration of the drug. On the two nights previous to the time of death she had had a little cyanosis and difficulty in breathing, but as soon as she assumed the upright position it disappeared. The heart continued to pulsate for at least two minutes after the cessation of respiration, and at the time of the cessation of the respiratory act the heart was in fairly good condition, excepting that the pulse was a little accelerated. The treatment given was: Hypodermics of atropine, strychnine, and the administration of oxygen. At the same time external heat was applied with friction to the surface of the body. While it was not possible to obtain an autopsy, it is certain that death was due to the scopolamine alone, as her organs had been very carefully examined by several physicians and found to be normal.

Gastrointestinal Disturbances Associated with Migraine.—J. A. Lichty refers to a paper previously published by him on this subject. The cases there reported, and those since observed, number 181. Of this number 137 gave a definite history of digestive disturbances between the attacks. The symptoms were definite, such as heaviness after eating, pyrosis, fermentation, and gas, constipation, or diarrhea; in fact, any or all of the symptoms which make the symptom complex of what is ordinarily called indigestion. In 101 of these cases gastric analyses were made. Twenty-five had normal secretion of gastric juice, thirty-two had an excessive secretion (hyperacid), and forty-four had deficient secretion (hypoacid). Many showed the evidences of chronic gastritis and enteritis. A few gave the history and had the clinical evidences of chronic ulceration of the stomach. His statistics show that the stomach contents in the majority of cases are not excessively acid, though the contrary fact has generally been accepted as true. No details of treatment are given. The author commends the use of the bromides and cannabis indica when the removal of reflex and exciting causes does not accomplish the desired results.

Post-Mortem Findings in Gastric Ulcer.—M. R. Barker states that the findings of the greatest importance are those connected with mucous membrane of the pylorus and the pyloric orifice. If the ulcer has been the direct cause of death, the mucosa is swollen and deeply hyperemic, while that of the fundus shows no abnormality. It is not, however, uniform. It is deepest at the orifice and about the ulcers, gradually fading out towards the wider portions of the stomach. Generally but one ulcer is present. Large ulcers indicate a fusion of several small ones. Appearances differ, according to the age of the ulcers. If the ulcer is recent its walls are not elevated, they are soft to the touch, and somewhat ragged in appearance. In the older ulcers the walls are cicatricial tissue, firm and resisting to the touch, and slightly elevated above the surrounding tissues. The microscope shows the wall of the recent ulcer, and also its base infiltrated with round cells, while in the older ulcers a good deal of fibrous tissue is found in the walls. The walls of the gastric ulcer slope towards the center of the ulcer, showing that the deeper structures involved are not so widely involved as the superficial structures, and when these ulcers extend deeply into the tissues they have the appearance of a cone, the base of which is on the surface, with the apex deep in the tissues. In addition to the foregoing post-mortem findings on the mucous membrane of the pylorus, ciatrices are sometimes found, marking the location of the former ulcers which have healed. The muscular coat of the organ is generally unaffected, unless there has been marked pyloric stenosis, which is more or less hypertrophied. Lesions in surrounding tissues are conditioned on the fact of the penetration of the stomach wall by the ulcerous process. The size of the organ, as a whole, is not markedly affected. Local constrictions may be present, due to previous ulcers which have healed. Ulcers involving only the mucous membrane of the stomach heal without forming cicatrices, only the ulcers involving the deeper structures heal with the formation of scars. Hence, these post-mortem findings teach that deep and wide ulcers of the stomach heal, but that in some cases, as in hour-glass contraction, the healing of the ulcer has in no way benefited the patient, as the contracture formed is as great a menace as the disease which produced it. In other cases, distortions of the stomach have been found which have so changed the relations of one part of the stomach to other parts of it, and to the organs about it, that it could not functionate normally. Hence, the conditions caused by the healing of ulcers are sometimes as vicious as the ulcers themselves.

The Radical Mastoid Operation Modified to Allow the Preservation of Normal Hearing.—W. S. Bryant notes that in cases of acute extensive involvement of the temporal bone, and more rarely cases of chronic purulent otitis media, the intactness of the sound-conducting apparatus has been more or less preserved, so that the hearing has been fairly good. It is his aim to preserve this hearing, in spite of radical intervention. The aim is to remove all diseased bone and establish perfect drainage, while at the same time preserving the auditory function of the middle ear. The ligamentous attachment and mucous membrane reduplications of the ossicular system lie between the epitympanum and the atrium, and prevent through drainage, though they allow drainage from both their upper and lower surfaces. To establish this drainage, we make a U-shaped myringotomy to drain the atrium, and open the mastoid antrum to drain the epitympanum. We must also remove all the diseased bone to arrest the progress of the infection and open all the cells of the middle ear system to throw them into one cavity leading to the epitympanum. The outer anterior wall of the antrum should be wholly taken away, except enough to support the annulus with the adjacent membrane tympani. Of course, the suspensory ligament of the malleus must be protected from injury, also the fan-shaped ligament of the incus. By these procedures we are able to drain the upper and back part of the tympanum through the mastoid wound, and the lower anterior part through the meatus without permanent injury to the sound-conducting mechanism. The operative course in one case is described and illustrated.

Journal of the American Medical Association, October 27, 1906.

The Physiology of the Circulation.—J. Erlanger discusses the facts so far ascertained in regard to the physiology and pathology of blood pressure and the path of conduction of impulses between the auricles and ventricles of the heart, and discusses the various methods of determining the systolic and diastolic pressures in man. He gives reasons for considering estimations of both as of clinical and physiological value, and calls attention to the relations of blood pressure to the phenomenon of Cheyne-Stokes respiration, noticing especially the recent work of Eyster, who has shown that, besides the type associated with increased intracranial tension, there is also another form associated with arteriosclerosis, myocarditis, and nephritis. The second part of the paper discusses the question of the path of conduction of impulses from the auricles to the ventricles in the mammalian heart. The discovery of the auriculoventricular bundle of muscular fibers, section of which causes independent action of the auricles and ventricles, is noticed, and the author's method of experimentation on the production of heart block is described. Erlanger also mentions the possibility of heart block occurring from other causes than obstruction of the passage of impulses from auricles to ventricles, and says that a definite answer to the question of what is the cause of heart block in man cannot be given in the present state of our knowledge. All we

are justified in saying is that disease of the auriculoventricular bundle has been found in all cases, now four in number, which have come to autopsy since it has been proved that that bundle forms the only physiological nexus between the auricles and ventricles of the heart.

Chorea.—W. S. Thayer concludes that the occurrence of well-marked febrile symptoms, without rheumatism, in chorea, especially if they are accompanied with undue rapidity or irregularity of the pulse, is at least strongly suggestive evidence of acute endocarditis. It is possible that the fever may be the sign of a deeper lying infection back of the chorea, but there is nothing in his study to settle the question whether chorea represents a secondary infection or a special localization of an infectious agent responsible for essential manifestations of the disease. The study of the circulatory conditions in old patients still remains to be carried out, but Thayer calls attention to the following points of interest thus far developed in his investigation: 1. Of 689 cases of chorea observed at the Johns Hopkins Hospital and Dispensary during one or more attacks, 25.4 per cent. showed evidences of cardiac involvement; such evidence was present in over 50 per cent. of the patients studied in the wards of the hospital. 2. Cardiac involvement occurred with somewhat greater frequency in those cases in which there was a history of acute polyarthritis than where such history was absent. 3. Cardiac involvement was commoner in cases of chorea with frequent recurrences than in those in which there was a history of a single attack. 4. In 110 cases of chorea treated in the wards of the hospital there was fever of a moderate extent in almost every instance. 5. In the large majority of the cases in which high fever was present there was evidence of cardiac involvement. 6. There is good reason to believe that the presence of fever in otherwise uncomplicated chorea is, in a large proportion of cases, associated with a complicating endocarditis.

Cardiac Hypertrophy in Renal Disease.—N. B. Potter reviews the literature and theories of the cardiac hypertrophy in nephritis, which seems to be probably the result of a compensatory increased vascular tension, and this depends largely on the general condition of the patient's nutrition. The recent autopsy records of the New York Hospital, which are quoted, seem, on the whole, to bear out this view. The therapeutic indications deducible from these facts are summarized as follows: "We should, of course, first and always, work against the cause, next favor hypertension, or, at least, not combat it early in the disease; then preserve and save the heart by every known method, particularly by limitation of fluids ingested, as von Noorden has urged; and, finally, keep up the patient's nutrition by every possible means, so that as perfect and permanent a compensation as possible may result."

Medical Specialism.—L. H. Adler, Jr., defends the specialists, and asks would the public health be as well guarded if we trusted entirely to the general practitioner in all possible medical conditions, or could the best interests of medicine be thus conserved? The ideal specialist, in Adler's opinion, is the man who, after a full term of residency in a general hospital, takes up general practice with a definite idea that in the future he will take up some special line which his tastes or the course of events dictates. When possible, an association should be formed with a specialist, and he also believes that at least a year's post-graduate study in the medical centers should be undertaken. Specialism, in his opinion, is a need developed by the times, and he thinks that the apparent antagonism that exists in some quarters could be prevented by more cordial and careful consideration on the part of the specialist of the patient's family physician. Specialism, he thinks, is an advantage to the general practitioner who has the opportunity of reading or hearing the papers and discussions of the specialists. In conclusion, he pleads for due ethical treatment of errors that may be observed. No one is infallible.

Surgical Tuberculosis.—H. B. Gessner points out that practically every organ and region of the body is subject to tuberculous invasion that may demand surgical treatment. The rare tuberculous lesions of the endocardium are beyond the surgeon's reach, as would also be those of the large vessels, did they occur primarily; but apart from these it can hardly be said that there is any other locality where surgical relief of such lesions can be said to be impossible, at least in the future. The diagnosis of surgical tuberculosis by modern methods, exploratory puncture and examination of the fluid by staining, culture, and inoculation, is rendered a matter of only ordinary difficulty. Gessner has found tuberculin a useful aid, but cautions against the use of excessive doses. As regards prognosis, he is optimistic. Without neglecting hygienic measures, he holds that early recognition and proper surgical treatment make the surgical form of tuberculosis as hopeful as any class of lesions with which we are acquainted.

The Lancet, October 13, 1906.

The Prevention of Cancer Regarded as a Practical Question Ripe for Solution.—C. B. Keetley believes that cancer is due to some living organism. He is inclined to think that alcoholic excess, chronic gastritis, old gastric ulcers, and cicatrices predispose to the disease. Anything remedying or preventing these will lessen the occurrence of cancer. He lays down the following rules: (1) Sterilize the food; (2) make sufficient and regular toilet and protection of the nipples, and of the genitalia; (3) Give due care to the mouth and teeth; (4) Carefully destroy the dressings used on discharging malignant ulcerations, and do not allow them to pollute either the hands or underlinen; (5) Cure all nonmalignant sores, and do not allow them to drift on to a chronic stage; (6) Excise early all cancerous and doubtful tumors and ulcers; (7) Abstain from tobacco, alcohol, and from foods which leave waste products, of which the kidneys, the bowels, and the skin cannot easily and thoroughly get rid, and which provoke and sustain the chronic inflammations and ulcers which so often pave the way for cancer. This rule forbids, among many other dietary abuses, the excess of meat eating; (8) Avoid physical familiarity with all as far as possible. We get the majority of our diseases either directly or indirectly from one another and the more exclusive our intercourse, whether innocent or otherwise, the safer we are. Even those who will deny that this is true of cancer may acknowledge that it applies to some of those chronic diseases which prepare the ground for cancer; (9) Housekeepers should be careful as to the service, as well as to the cooking of food.

Contribution to the Pathology of Chorea.—This subject is considered by F. J. Poynton and G. M. Holmes, whose investigations add three more cases to the recorded observations of the presence of a diplococcus in the pia mater of patients who have died from brain trouble while suffering from chorea. The organism has been demonstrated in the brains in these cases in the perivascular spaces and connective tissue. They have also studied the changes affecting the connective and vascular tissues and those which occur in the nervous tissues in chorea, and, finally, they have demonstrated that in a case of chorea occurring during the first pregnancy, lesions were present similar to those found in the rheumatism cases. The histories of the three brain cases, above referred to, are given in full. The authors believe that chorea is caused by toxins, which penetrate the brain by direct bacterial invasion. They do not consider themselves in a position to state what portion of the nervous system yields the predominant symptoms of chorea. It has been assumed to be the higher motor centers in the cerebral cortex. As regards chorea and rheumatism, they state that the cause of the former is to be in the action of bacterial poisons on the brain. Further, the available evidence points to the occurrence of a local infection to which the widespread changes in the nervous system are due. Finally, they believe that this infection is of a rheumatic nature. As to the relation between chorea and pregnancy, two questions arise; first, whether this chorea is a rheumatic chorea intensified by the condition, and secondly, a far wider one concerned with the influence of pregnancy and the puerperal state upon the rheumatic infection. Chorea in pregnancy is, in the opinion of the authors, probably a rheumatic chorea.

British Medical Journal, October 13, 1906.

Mesenteric Cyst Causing Intestinal Obstruction.—F. Colby reports the case of a boy of twelve years with acute intestinal obstruction. Abdominal incision revealed a cyst the size of an orange, situated between the layers of the mesentery as they separate to enclose the bowel, and the bowel itself was compressed like a piece of ribbon over the circumference of the cyst wall. The cyst (which contained cholesterine) was shelled out, and the patient made a perfect recovery.

Bone Formations in the Heart.—J. A. Topham refers to the case of a man of seventy-one years with a dilated heart, who died in an attack of syncope. Autopsy showed the heart large and flabby, the muscle undergoing fatty degeneration. It weighed 18¼ ounces. Some masses, hard and stony to the touch, lay trans-

versely across the organ in the line of the auriculo-ventricular groove. On cutting down to these they were found to be flattened plates of bone, embedded in the cardiac tissue, having a firm fibrous covering which proved very difficult to detach. One, the larger, 4 inches in length and 1 inch across throughout the greater part of its length, but widening to 2 inches at its right extremity, lay with its flat surface looking forwards, embedded in the wall of the heart, about half an inch from the surface, with its long axis parallel to the line of the right auriculo-ventricular groove. In a similar position on the left side were two smaller fragments, flattened, but irregular in outline, and each about 1 inch by 1½ inches at their greatest diameters. The aorta and orifices of the coronary arteries had a healthy appearance.

Pneumococcal Infection During Early Life.—H. Ashby's contribution forms the opening discussion in a consideration of this topic at the recent Toronto meeting of the British Medical Association. He says we may assume that the pneumococcus of Fraenkel is the specific agent which, under suitable conditions of soil, is the inciter of a croupous or lobar pneumonia, and that, in association with other organisms, it plays the chief rôle in bronchopneumonia and in the pneumonias which occur as sequelæ of the zymotic diseases. We may assume, too, that a pneumonic infection is not a local disease of the lungs, but the cocci enter the blood stream, multiply there, and are carried to distant organs. For a pneumonic infection to produce pathological consequences a sufficient number of organisms must infect; these must possess, or quickly attain, high potency, and finally, there must be an enfeebled resistance of the body cells of the individual. In healthy people, the probable breeding place is the nasopharynx and its vicinity. While pneumococci are associated with streptococci in healthy nasopharynges, they are not found in the blood stream except in pathological conditions. A bronchopneumonic occurring in infants or young children, especially when associated with rickets, terminates by lysis rather than by crisis, is protracted in its course, and is apt to relapse. A pneumococcic infection involving the lungs in the first instance is more apt to spread to parts locally in contact (pleurisy, pericardium) than to distant parts by way of the blood stream. Associated infections of the lung and peritoneum are not uncommon. Acute pneumococcal peritonitis in infants under one year, proving quickly fatal and without any associated pneumonia, is not uncommon. It is uncertain to what extent gastroenteritis is caused by this organism. The jaundice of pneumonia is probably hematogenous. A lobar pneumonia, in association with acute nephritis, is not rare. Double otitis with pneumonia is frequent. The organism frequently gives rise to a meningitis. Ashby declares that as yet we know but very little about mixed infections, the nature of the toxins thus formed, and the question of immunity.

Rheumatism in Children.—A. D. Blackader notes that the purely arthritic manifestations of rheumatism in children may be wanting, and the disease appear as tonsillitis, chorea, pleurisy, muscular pain, exudative erythema, and epistaxis. Special attention is paid in the paper to the question of tonsilitis. Authorities differ as to the exact type associated with rheumatism. Anemia is a constant manifestation of the rheumatic infection. Other manifestations are pleurisy, severe and persistent headaches, and enuresis, but the most important at every period of life is the development of "carditis," and many writers have emphasized the fact that during childhood the cardiac tissues are particularly susceptible to the rheumatic poison. Statistics from English hospitals show that in about 80 per cent. of those attacked in the first decade, and 60 per cent. in the second decade of life, the heart is to a greater or less extent permanently crippled. In the hospitals on the Continent the percentage is very similar, but the severe grade of carditis described by English writers, leading to rapid dilatation of the heart from the action of the toxin, is, in the author's experience, rarely seen. On account of this liability, any manifestations of a rheumatic infection demand rest for the child in bed, and frequent physical examination of the cardiac area. It is not to be forgotten that an endocarditis may develop with little alteration in pulse and temperature. The endocarditis of childhood with care, however, presents a distinctly better prognosis than does a similar lesion in the adult, and not a few cases of soft systolic murmur, in which, so far as can be judged, dilatation and anemia as causes have been excluded, will in children pass entirely away with time. On the other hand, we must bear in mind that in a few cases hearts which, from the absence of, or on account of the disappearance of, physical signs, have apparently escaped damage, may with passing years present undoubted signs of organic trouble.

Berliner klinische Wochenschrift, October 8, 1906.

The Hot-Air Treatment of Emphysema, Chronic Bronchitis, and Bronchial Asthma.—Cohn-Kindborg investigated the effect on the lungs of the application of hot air to the thorax, and concludes that, contrary to the belief expressed by some observers, the procedure lessens congestion of the lung, instead of causing hyperemia. An apparatus devised by the author for applying hot air in this way is described and figured. The author made use of this in twelve cases of emphysema with chronic bronchitis, and in six cases of bronchial asthma. Most of these were of unusual severity, yet the most satisfactory results were obtained in nearly every instance. The temperature in the interior of the apparatus ranged from 65°C. to 85°C., which latter point appeared to be the upper limit which it seemed desirable to employ. The improvement resulting included the subjective amelioration of the dyspnea, and also diminution in cough and expectoration, better rest at night, and increase in the vital capacity of the lung.

Barberio's Semen Reaction.—Levinson reports on investigations undertaken to determine the reliability of the picric acid test for semen described by Barberio. The reaction consists in the formation of characteristic acicular yellow crystals somewhat resembling Charcot-Leyden crystals when saturated aqueous or alcoholic picric acid solution is added to semen, or a concentrated watery extract of it. The author found that the reaction was positive in all cases in which spermatozoa were present, and that it was sometimes, though not always, positive in cases of azoospermia. A large number of other fluids and secretions, which in medicolegal work might be of importance in this connection, were also tested, but none of them gave a positive result. It also appears that the semen of none of the commoner animals or fish gives the reaction, and the author believes that further investigation will prove it to be a valuable addition to forensic medicine.

Münchener medizinische Wochenschrift, October 9, 1906.

The Manufacture of Catgut.—Kuhn, in describing the various procedures through which the raw material is put in the manufacture of catgut, points out in how many respects improvements are urgently demanded. What is used for surgical purposes consists of defective material which is not considered sufficiently good for the production of violin strings. The raw material is handled under the most unsanitary and, from the surgical standpoint, dangerous conditions, no care being taken to determine the freedom from disease of the animals from which it is derived. A very important drawback lies in the manner in which the larger sizes are prepared by twisting together several of the smaller strands of gut, whereby any impurities on these are deeply buried in the center of the thread where their sterilization is exceedingly difficult. The author proposes that catgut for surgical use should be prepared only from officially inspected slaughter animals, that all manipulations in the process of cleansing and preparing the gut should be carried out by properly trained individuals under aseptic precautions, and that the components of larger strands should be rendered aseptic before being twisted together.

Primary Ether Anesthesia.—Sudeck has modified his technique of operating under primary ether anesthesia as described by him some years ago. At that time he caused the patient to inhale as deeply and rapidly as possible the concentrated vapor from a mask on which 30-50 gm. of ether had been poured at once. Sudeck now considers this method unnecessarily heroic, and states that he has been able to obtain equally good results by the drop method. An open mask is placed in position, and the patient is allowed to draw a few breaths through it before the administration of the anesthetic is begun. At first one drop is allowed to fall every two or three breaths, gradually the rate of the flow is increased to a drop with every breath, and, as toleration is established, rapid dropping is begun. The patient's sensibility is tested by using alternately the point and head of a pin, and causing him to specify sharp or blunt. When the answers become incorrect the time to operate has arrived. Sudeck states that when properly carried out failure is encountered only very rarely. When the method is successful the patient is still sufficiently conscious at the beginning of the operation to obey the commands of the operator, and, if he wishes, to observe all the steps of the operation.

He experiences no pain, but only tactile sensations, and immediately on the termination of the anesthesia is able to arise without any disagreeable sequelæ.

Natural Disinfection of the Intestine.—Moro points out the inadequacy and undesirability of attempts at intestinal disinfection by the administration of antiseptic drugs, or even of calomel, and emphasizes the desirability of devising some method which should be in harmony with the natural defensive forces of the organism. The stool of the breast-fed infant presents as its predominating bacterial component the *Bacillus bifidus* of Tissier and the extreme activity and great vitality of this organism enable it rapidly to overgrow all other bacteria that may be present in the intestine. The author has found that a most efficient means of ridding the gut, both of children and of adults, of undesirable bacterial guests consists in the administration of human milk. In a surprisingly short time the *Bacillus bifidus* will have overgrown all of its competitors. While at present the method is difficult of application on account of the scarcity of breast milk, it seems likely that it will be possible to discover the particular substance in this fluid which is so advantageous to the organism in question, and in that case the problem might be simplified.

Deutsche medizinische Wochenschrift, October 11, 1906.

The Indications in the Management of Labor in Cases of Contracted Pelvis.—Pfannenstiel believes that pubiotomy has come to stay, and that in hospital obstetrics, at least, it will in future be a routine procedure. For private practice the operation is less well adapted, however. The use of forceps, he says, is least satisfactory in the flat pelvis, but gives better results in the generally contracted pelvis. Version, on the other hand, gives less good results in the generally contracted flat pelvis, and is most effective in the flat pelvis. It is particularly suitable for multiparas with flat pelves, because under these conditions the soft parts are easily dilatable. Pubiotomy must be considered in those cases in which the disproportion is so great that perforation of the living child would be required. The lower limit with a flat pelvis and full-sized fetus would be a true conjugate of 7 cm., and in the generally contracted pelvis a conjugate of 7.5 cm. If the pelvis is smaller than this, cesarean section is indicated. The early induction of labor is indicated in the flat pelvis with a conjugate of 7.5 cm. as the lower limit, and 8 cm. in the generally contracted pelvis. Generally contracted flat pelves are usually not suitable for the induction of early labor, but require pubiotomy or cesarean section. In the flat pelvis labor is best induced by the use of the metreurynter, but in the generally contracted pelvis the bougie method is preferable, because it is undesirable to run the risk of displacing the presenting part.

Chronic Appendicitis.—Oberndorfer differs from those who believe that a true chronic appendicitis does not exist, and that in all cases an acute inflammation has preceded any long-standing process. Oberndorfer is of the opinion that a true chronic interstitial inflammation of the appendix, originating in the lumen of the organ, occurs as a result of bacteria or their toxins. This chronic interstitial inflammation begins with swelling of the follicles, together with a proliferation of the young connective tissue cells in the inner layer of the submucosa. As a result of the increased density of the submucosa, and the consequent cicatricial contraction of the connective tissue, this layer is separated from the muscle, and the resulting space is filled with fat. At the same time compression and atrophy of the mucosa is caused. The final stage of the process is a partial or total obliteration of the appendix, always beginning at its tip. If concretions are present in the lumen of the tube its walls cannot collapse, but the submucosa becomes thickened, the mucosa atrophies, and the glands are partly destroyed. A very marked increase of the elastic elements compensates for the degeneration of the contractile structures.

Primary Tuberculosis of the Spleen.—Frank calls attention to the existence of this condition, which, he states, is usually overlooked. In cases of splenic tumor, in which all of the ordinary etiological factors, such as leukemia, pseudoleukemia, malaria, syphilis, and alcoholism, may be excluded, and in which the enlargement of the spleen is the only evidence of disease, he considers it justifiable to resort to the injection of tuberculin. If the result is not conclusive exploratory laparotomy should be done without undue delay. The extirpation of a tuberculous spleen is not only warranted, but is called for, since all of the cases so far reported have resulted favorably.

French and Italian Journals.

Contribution to the Morphology of the Hypophysis of the Brain.—N. C. Paulesco presents the following conclusions: 1. Among the various animals of the vertebrate series the best ones for use for the total ablation of the hypophysis in the physiological laboratory are the frog, the hen, the cat, and the dog; 2. In the dog and in the cat the extirpation by itself of one or the other of the two lobes, nervous and epithelial, of the hypophysis presents serious difficulties. The nervous lobe may be separated, but there is always taken off at the same time the medullary substance of the epithelial lobe which covers it. As to the epithelial lobe it cannot be taken out or entirely destroyed—the nervous lobe remaining intact—on account of the fragility of the tissues, and especially on account of the close proximity of the carotids; 3. The existence in the epithelial lobe of two parts, the medullary and the cortical, suggests a resemblance to the thyro-parathyroid apparatus, the cortical part corresponding to the thyroid gland, and the medullary part to the parathyroid glands. Aside from this there exists histologically manifest analogies between the corresponding parts. Although in the dog and in the cat it is unfortunately impossible to separate the two lobes perfectly, nevertheless, by the use of the thermocautery the greater part of the cortical substance can be destroyed. By this process one may hope to produce phenomena associated with functional insufficiency of the cortical substance. Again, by taking out the nervous lobe, and with it a large part of the medullary substance, one may hope to obtain phenomena associated with functional insufficiency of the medullary substance. In separating the hypophysis from its surroundings, the extent of the injury to the blood-vessels will depend upon the method of this procedure.—*Revista Stiintelor Medicale*, May-June, 1906.

Aneurysm of the Aorta Ruptured into the Pericardium.—Simon and Bénard studied this case at autopsy. The patient was a man sixty years old, a syphilitic, badly nourished. Two days before his death he had had a short attack of syncope preceded by dyspnea and precardial distress. At the end of a few minutes, however, he had been able to sit at the table for a meal. On the next day, still feeling pain, he entered the hospital. There it was determined that the heart-beat could be felt at the right of the sternum, and that the cardiac dullness extended over an area as large as the hand, as well to the left as to the right of the sternum. On the next day, two days after the first attack of syncope, the patient succumbed within the space of a minute and a half. The writers who were present at the time believe that the stopping of the heart preceded the cessation of the respiratory movements. At autopsy the pericardium was found to be very much distended. The aorta showed an enormous aneurysm, which was entirely enveloped in the fibrous sac of the pericardium. The aneurysm showed a rupture about one centimeter long. This rupture had probably taken place in two stages.—*Bulletins et Mémoires de la Société Anatomique de Paris*, April, 1906.

Post-exanthematous Cutaneous Tuberculosis.—H. Gougerot, after making a careful study of this subject, concludes that after measles, more rarely after scarlatina, there sometimes develops disseminated cutaneous tuberculosis distributed over the entire surface of the body. This occurs during convalescence or a little later. All of the cases reported have been noted in children from three to twelve years old. The morphological types are diverse. The one most often observed is the lupus of Willan, with its different forms. There has also been observed scrofuloderma, verrucose tuberculosis, and lichen scrofulosorum. The writers give a number of illustrative cases. They touch upon the association between smallpox and cutaneous tuberculosis. They believe that eruptive maladies predispose to cutaneous tuberculosis, particularly in the serious disseminated forms (measles, scarlatina), and that they aggravate lesions already existing (smallpox).—*Revue de Médecine*, September, 1906.

Roentgen Rays in Leukemia.—Rafaelle Pirone describes the treatment of a case of leukemia with Roentgen rays, and its effects on the blood of the patient. There was a sensible diminution of the leucocytes in the blood, and the relations of the various kinds were changed. The neutrophile myelocytes diminished, while the polynuclear neutrophiles increased. The red corpuscles and the hemoglobin increased. The myelogenous forms of leukemia are most benefited by the rays, while the lymphatic forms are not affected by them. The rays aid the transformation of myelocytes into polynucleated cells, of the erythroblasts into erythrocytes; in other words, they return to its normal condition the disturbed blood-producing function. The treatment of leukemia by the rays is not only a symptomatic treatment, but a rational one; on the other hand, it is not a specific for the disease.—*La Riforma Medica*, August 4, 1906.

Book Reviews.

THE PRACTICE OF PEDIATRICS, in Original Contributions by American and English Authors. Edited by WALTER LESTER CARR, A.M., M.D., Consulting Physician to the French Hospital, New York; to the New York Eye and Ear Infirmary; Visiting Physician to the New York City Children's Hospitals and Schools; Member of the American Pediatric Society; formerly Editor of the *Archives of Pediatrics*. Illustrated with 199 Engravings and 32 full-page Plates. Philadelphia and New York: Lea Brothers and Company, 1906.

THIS book, which is one of the three volumes of the "Practitioner's Library," the others being on Obstetrics and on Gynecology, is the work of fourteen contributors, most of them well-known pediatrists, and all clinicians of experience. In his arrangement of subjects the editor has wisely given prominence to those which belong purely to the domain of pediatrics, omitting for the most part a consideration of the diseases which are common to all periods of life, except in those cases in which the youth of the patient so modifies the course or the symptoms of a disease as to make of it a malady peculiar to childhood. The result of this skilled editing with the cooperation of the contributors has been to produce one of the best treatises on pediatrics which it has been our pleasure to see. The work is divided into twelve sections, dealing respectively with "Diseases and Injuries of the Newborn," "Development, Growth, and Hygiene," "Infant Feeding," "Diseases of the Alimentary Tract," "Diseases of Nutrition," "Infectious Diseases," "Diseases of the Respiratory Tract," "Diseases of the Heart and Blood-vessels," "Diseases of the Genito-urinary System," "Diseases of the Blood, Lymphatic System, and Glands," "Diseases of the Nervous System," and "Diseases of the Skin." The illustrations are of a high order, many of the plates especially being excellent. We can warmly recommend this well-written, well-edited, and well-printed volume to anyone who is in need of a thoroughly practical and up-to-date treatise on the diseases of children.

TECHNIQUE DU TRAITEMENT DES TUMEURS BLANCHES. Par F. CALOT, chirurgien en chef de l'Hôpital Rothschild, de l'Hôpital Cazin-Perrochaud, de l'Institut orthopédique de Berck, etc. Avec 192 figures dans le texte. Paris: Masson et Cie, 1906.

THIS is the third volume of Calot's treatise on orthopedic surgery, and deals with "White Swelling." The author refers to the ordinary conservative treatment of this affection, and condemns it as being too uncertain in its results and as consuming too much time. He also notices the operative method which, he says, "rarely cures, often makes matters worse, and always mutilates." In opposition to these methods, he urges intraarticular injections, and claims that a cure is effected by this mode in about 99 per cent. of cases, and this in a short space of time. The author uses two different solutions for injection into the joint, one of which will cause ankylosis and the other results in a movable joint. He goes into considerable detail as to the solution to be used, the dose, frequency, and all the *minutiæ* of the technique. The results claimed are certainly marvelous; and the book, which is most readable, should appeal to all who are interested in this subject.

AIDS TO PHYSIOLOGY. By PEYTON T. B. BEALE, F.R.C.S., Eng., Examiner in Physiology to the Society of Apothecaries; Lecturer in Physiology and Histology, Woman's Department, King's College; Demonstrator of Histology (Late Physiology), King's College, London. New York: William Wood and Company, 1906.

THIS is the newest compend on physiology, and is of a very elementary nature. In some parts it is deficient to the extent of being inaccurate; for example, all that it has to say of human milk is that "it contains rather more sugar and a larger proportion of water than cow's milk." The book is not up to the level of the other volumes of the Students' Aids Series.

LE SIGNE DE LA MORT RÉELLE EN L'ABSENCE DU MÉDECIN. La constatation et le certificat automatiques des décès (procédé de la réaction sulphydrique). Moyen simple, infaillible, à la portée de tous, pour éviter le danger de la mort apparente à la campagne. Par le Docteur ICARD (de Marseille), Médecin de l'Administration des pompes funèbres, Vice-Président de la Société de Londres contre le danger des enterrements prématurés, etc., etc. Avec gravures dans le texte. Paris: A. Maloine, 1907.

THE fear of being buried alive is a very real one with many people. In this little book Dr. Icard proposes a simple and ready plan to show conclusively whether death has or has not occurred. Among the earliest signs of commencing decomposition is the formation in the lungs of sulphurous vapors (sulphuretted hydrogen), which escape through the nasal fossæ. The author suggests that on a small piece of white paper a word or two should be written with a solution of lead acetate. The writing is invisible. The paper is then inserted within the nostril, and the certainty of death will be shown by the writing becoming dark, and therefore visible. It is claimed that this reaction is apparent at the end of about twenty-four hours; it is, therefore, a relatively early sign of certain death. The book deals with an important subject, and is worth reading.

SUPPLEMENTARY ESSAYS ON THE CAUSE AND PREVENTION OF DENTAL CARIES. By J. SIM WALLACE, M.D., D.Sc., L.D.S., Hon. Dental Surgeon, West End Hospital for Nervous Diseases, and Assistant Dental Surgeon, National Dental Hospital, W. London: Baillière, Tindall & Cox, 1906.

THE author has gathered together in this volume a number of essays which have appeared before. He discusses the cause of the prevalence of dental caries and its prevention, as well as the solution of the problem of susceptibility and immunity to dental caries. The main contentions which have been made now for some years by the writer have been corroborated by laboratory tests. The question of food selection is treated with a broad outlook and is one of the most interesting problems considered.

OUTLINES OF PRACTICAL SANITATION, for Students, Physicians, and Sanitarians. By Dr. HARVEY B. BASHORE, Inspector for Pennsylvania Department of Health, Author of "Outlines of Rural Hygiene" and "The Sanitation of a Country House." With 42 Illustrations. New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1906.

SUCH rapid strides are being made in the science of sanitation that a new book on the subject, or a revision every year, will no more than keep abreast of the times. The writer emphasizes the fact that he does not follow the beaten track of the usual sanitary textbook. Subjects are introduced here which are of interest not only to health officials, but also to taxpayers and citizens. Among these subjects are milk and food supplies, and car sanitation. These are topics which are exciting the most general interest. In other chapters are discussed the subjects of habitations, including hospitals, prisons, asylums, and theaters; water supply, its storage, distribution, purification, and examination; the collection and distribution of waste; the cause and prevalence of contagious and infectious diseases; vital statistics; municipal sanitation; rural and suburban sanitation; and personal hygiene. A very satisfactory index completes the volume.

A TREATISE ON SURGERY. By GEORGE RYERSON FOWLER, M.D., Examiner in Surgery, Board of Medical Examiners of the Regents of the University of the State of New York; Emeritus Professor in the New York Polyclinic, etc. Vol. II. Philadelphia and London: W. B. Saunders Company, 1906.

WE reviewed recently the first volume of the late Dr. Fowler's book and we are pleased to find that the good qualities commended in the first are repeated for the second volume, which now completes the treatise. The second volume is devoted to the surgery of the vertebræ, the abdominal and pelvic cavities, and the extremities. Particular interest attaches to the section on abdominal surgery, including as it does a description of the numerous features with which the author's name is associated. This section is very complete and well illustrated. It is strange that here, as well as in most other surgical textbooks, the technique of introducing a Murphy button should differ in some essential detail from that described by Murphy himself, and the method here shown also differs from that described in Murphy's original paper in the MEDICAL RECORD. Fowler's description of appendicitis is concise and practical, and the technique of the operation does not contain a multitude of "stunts" to confuse the reader. The remainder of the book is equally satisfactory, and the work as a whole will take a leading place among recent surgical textbooks.

GYNECOLOGY. Vol. IV of The Practical Medicine Series, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of GUSTAVUS P. HEAD, M.D.; Vol. IV, edited by EMILIUS C. DUDLEY, A.M., M.D., Professor of Gynecology, Northwestern University Medical School, etc., and C. VON BACHELLÉ, M.S., M.D., Gynecologist to the German Hospital, Chicago. Series 1906. Chicago: The Year Book Publishers, 1906.

THE volume on gynecology of this most compact and practical series of manuals presents the same features as have been already noted for the preceding volumes. The field has been very well covered, and the illustrations—many of which are taken from recent publications—are excellent. The volume should prove indispensable to every practitioner interested in the progress of gynecology.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 22, 1906.

Dr. Floyd M. Crandall in the Chair.

The one hundred and first annual meeting was called to order by the President, Dr. Crandall, who declared the polls opened for the election of officers, censors, and delegates.

Report of the Comitia Minora.—Dr. John Van Doren Young presented this annual report. There were 2,280 members, of whom 2,012 were in good standing.

Report of the Treasurer.—Dr. Charles H. Richardson presented this annual report.

Report of the Board of Censors.—Dr. Cornelius G. Coakley presented this annual report.

Report of the Committee on Discipline.—Dr. Edward D. Fisher said this committee had not been called upon to act during the past year, therefore he had no report.

Report of the Committee on Audit.—Dr. Matthias L. Foster presented this annual report.

Report of the Milk Commission.—Dr Roland G. Freeman said it was just six years since the organization of the milk commission under the auspices of the society, and he briefly reviewed what it had accomplished. After the appointment of the commission in 1900, the work of interesting dairymen was undertaken. Considerable progress was made possible through the cooperation of the Rockefeller Institute and the City Board of Health. The former undertook the expense of inspection while the latter provided facilities for bacteriological examinations. This movement created a demand on the part of the public for milk supervised by this commission, so that at the end of the first year, when the aid of the Rockefeller Institute was withdrawn, the dairymen saw that it was to their advantage to contribute such amounts as were necessary in order to support the machinery of the commission. At the end of the first year the commission was enlarged, new rules for the production of certified milk were elaborated, and a second grade of supervised milk, which could be produced at less cost, called inspected milk, was authorized. By the end of the second year 3,000 quarts of certified milk were being produced daily on nine farms and sold by nine dealers in New York. A considerable amount of inspected milk was also marketed. The following year ten farms were producing 4,300 quarts of certified milk and 1,500 quarts of inspected milk, a total of 5,800 quarts. The next year twelve farms were producing 5,138 quarts of certified milk which were being sold by ten dealers, while 3,040 quarts of inspected milk were marketed. In 1905 fifteen farms were producing 7,062 quarts of certified milk which were being sold by thirteen dealers, and this, together with 3,240 quarts of inspected milk, made a total output of 10,302 quarts, and the number of visits to the farms by the inspectors had increased to 208. This year 9,567 quarts of certified milk were produced daily on nineteen farms and sold by thirteen dealers, which, together with 2,800 quarts of inspected milk, made a total of 12,367 quarts, while the number of visits to farms had increased to 329. During these years the interest of the dairymen had made it possible to have somewhat more rigid requirements for the production of this milk. During 1903 a seal was adopted to prevent manipulation of the milk after it left the farm, and the farmers were required to stamp on the pasteboard cap the date of milking. During 1904 the tuberculin test, which had previously been recommended, was required, and during the same year postal cards were prepared on which the dairymen were required to send notification of any contagious disease on the place. More recently a set of fines had been established for neglect in complying with the requirements for the production of certified and inspected milk, and a score card for computing the excellence of the different dairies had been prepared and applied to the rating of the dairies. Inspected milk was sold in bottles for 8 cents a quart, while certified milk was sold at from 12 to 20 cents. That sold for 12 cents was produced in compliance with the requirements of the commission, while that sold at a higher price was often produced under extra precautions not required by the commission. The commission had assumed no control over the prices charged by the dealers and was not instrumental in the movement to raise the price of ordinary milk. The commission felt some pride in the results of its work. The commission asked the privilege of publishing this report so that the reprints might be used to answer the frequent inquiries received concerning its work.

Report of the Counsel of the Society.— Champe S. Andrews, Esq., made this report. He said the United States Post-Office Department, through Post-Office Inspector William H. Snow, had been of the greatest service to this department, increasing its efficiency and reducing expenses in certain lines of work. The Police Department of the City of New York deserved special praise and credit for its great assistance rendered during the past year. Col. Theodore A. Bingham, Police Commissioner, detailed a regular detective, Mr. Ferretti, to aid in their work. Through his assistance they were able to break the record of the legal work of the society. The amount of fines imposed and paid was larger than in any year of the society's existence. The attack against the abortion and personal columns in the papers that hitherto published them, had been completely successful. The papers of New York City were now absolutely clean so far as the advertisement of the abortionist was concerned.

Proposed National Society for the Preservation of the Public Health and Morals.—In the early part of this year Mr. Andrews lectured in Philadelphia by invitation of Dr. Henry W. Cattell; on this occasion Mr. Andrews elaborated upon the necessity of forming a national society composed not only of physicians but of men and women in every walk of life interested in the suppression of quacks and quackery. The Medical Society of the County of New York was the first to pass a resolution favoring the idea of the appointment of delegates from public-spirited societies to meet in the fall to devise ways and means to protect the public health and morals. This resolution was passed on the 14th of May, 1906. The idea was approved by many societies and letters from these sources endorsing the movement were printed in one pamphlet, together with proposed form of resolution authorizing the appointment of delegates to the conference to be held November 15 at the Hudson Theater, New York City. Over one hundred societies had joined in the movement and delegates were being appointed from all over the United States.

Resolution.—Dr. Henry S. Sterns offered the following resolution, which was unanimously adopted:

Whereas, During the past twelve months, for the first time in the history of the Medical Society of the County of New York, the public authorities have come to the assistance of its legal department in the enforcement of public health laws against quackery and charlatanism, and

Whereas, The efficiency of the work of the legal department of the society has been greatly increased and the protection of the general public been made much more effective; and

Whereas, The Postmaster-General, Hon. George B. Cortelyou, by directing certain Post-Office Inspectors, including Inspector William H. Snow, is the person directly responsible for the cooperation on the part of the Federal authorities; and

Whereas, Col. Theodore A. Bingham, Police Commissioner of the City of New York, through his detail of

Officer Andrew Ferretti, is directly responsible for the cooperation of the city authorities; now, therefore, be it

Resolved, That the Medical Society of the County of New York, at its one hundred and first annual meeting, express its profound thanks to Hon. George B. Cortelyou, Postmaster-General, and to Col. Theodore A. Bingham, Police Commissioner, for the great assistance they have rendered the society during the past twelve months, and ask for a continuance of the cordial co-operation to the end that the interests of the people may be protected against the ravages of quack and charlatan; be it further

Resolved, That a copy of this resolution be transmitted by the Secretary of the Society to the Hon. George B. Cortelyou, Postmaster-General, and to Col. Theodore A. Bingham, Police Commissioner of the City of New York.

Acute Pancreatitis; With a Report of Five Cases.—Dr. JOHN F. ERDMANN read this paper, which was a thesis for admission to membership in the American Association of Obstetricians and Gynecologists, meeting held in Cincinnati, September, 1906. After quoting from a recent article which appeared in the MEDICAL RECORD, January 20, 1906, on "Digestive Disorders and Abdominal Pain," he said that chemical analyses, as now understood in pancreatitis, were frequently misleading, and patients at present should be urged to submit to an abdominal section. It was far better that such an exploration be made, with its findings, than to wait for some complex urinary, blood, and digestive analyses. The chemistry of pancreatic disease was yet in its infancy and related chiefly to the feces and urine. The excreta contained in many instances globules of fat and partially digested muscular fiber. Should an analysis of feces be demanded in an acutely toxic case, one could see the loss of valuable time waiting for the stools, when an exploratory operation would promptly discover the condition and save life and time. Liquid fat had been expelled after normal stools, and the stools were said to be much larger than normal when compared to the amount of food intake. These two excreta evidences could be considered only in chronic pancreatitis. The urine had frequently been cited as containing sugar. He reported five cases, none having sugar at any time, either before or after the operation. Dr. Thayer of Baltimore in 1905 had reported five cases, none of which contained sugar. With these ten cases he was inclined to give no weight to the presence of sugar as a factor in acute pancreatitis. That the duct of Wirsung was a mode of entry of infection, etc., had been demonstrated on several cases, and in one of the hemorrhagic cases he reported presented two small biliary calculi in the duct of Wirsung. Traumatism, alcoholism, and arteriofibrosis were also factors. Opie had demonstrated a distinct relationship between gall-bladder disease and pancreatitis. Stones in the common duct might plug up the Vaterian papillæ, and a retrograde flow of infected bile might enter the open duct of Wirsung. In the five cases reported in his paper, three were hemorrhagic, one of them having the pancreas almost completely destroyed without slough formation, and two that resulted in abscess formation. None of these was accompanied by the discharge of any slough, although sloughing was one of the terminations of an acute inflammation of this viscus. The onset of this condition was usually a sharp pain accompanied with varying degrees of shock, rapidly followed in some cases by a profound toxemia, denoted or characterized by a peculiar cyanosis and lividity, with shallow breathing and rapid pulse. The pain was usually of a far more intense degree than that of appendicitis or gastric perforation. Hiccough was a symptom of relative frequency and persistence; there was vomiting with and following the pain onset. Pain in the back, of an intense splitting character, was evidenced in three of his cases. These symptoms, when considered with a history of previous digestive disturbances and gall-bladder or duct invasions, should cause one to give the possibility of pancreatitis great weight. The subsequent manifestations were those of an ordinary peritonitis, *i.e.* abdominal distention, obstruction due either to pancreatic pressure or intestinal paresis. Later, a tumor formation anywhere in the epigastrium, or rather supraumbilical zone. If in doubt, explore; if then one met with a peculiar bloody, beef-broth-like serum or peculiar warty, yellowish-white plaques (fat necrosis) upon the omentum or mesentery (provided no strangulation existed as a cause of this bloody serum), one could safely extend the search to the pancreas. If an acutely hemorrhagic, enlarged pancreas was found, an incision should be made in its coat of peritoneum and a puncture or punctures made in the pancreas itself. Gauze or other drains should be placed in about these incised and punctured areas. If gangrenous or suppurative, drainage sufficiently free to allow of ready expulsion of the sloughing material and drainage of the pus should be provided, either by the anterior route or in the costavertebral angle. The question of doing a cholecystotomy or not was one that each individual case itself would present for consideration. In the five cases reported, the gall-bladder was drained twice, each time for large numbers of stones. In one of the remaining cases it was palpated and inspected without being drained. In the remaining two cases it was not seen, owing to the pus collections being well to the left. The cholecystotomy cases died, while two of the remaining cases recovered, and the third died weeks later from exhaustion and multiple infective abscesses. None of the five cases had at any time any evidence of sugar in the urine. In conclusion, he called attention to some of the prominent symptoms, as follows: The marked pain at the onset; the sharp intoxication of some of the cases; the dyspnea and lividity seen in many; the constant, splitting backache; the indefiniteness and difficulties in the present state of the chemistry of the urine and feces. He emphasized the importance of early exploration when a given set of symptoms, such as were presented, manifested themselves.

Dr. JOHN B. WALKER said that these cases were seldom recognized, and in his experience he could report but two cases, one a woman of 40 years, the other a man of 50 weighing 170 pounds. The latter patient complained of pain in the epigastrium; there was none in the lower abdomen. He had no vomiting, increased pulse rate or temperature. The epigastric pain grew more intense, and then occurred a slight elevation of temperature, but not a very rapid pulse. Operation was declined until 60 hours after the onset of the attack. There was no leucocytosis and the bowels were not constipated. Sixty hours after the onset, an incision was made, and the peculiar yellowish-white plaques of fat necrosis, as mentioned by Dr. Erdmann, the peculiar bloody, beef-broth-like serum, were noted. Twenty-four hours later the man died. Dr. Walker emphasized the importance of an early recognition of these cases and the peculiar epigastric pain.

Dr. LEONARD WEBER said that in December last a rather healthy married woman, 35 years old, came to his office and told him that another physician had told her she had sugar in her urine. Dr. Weber found she had between 4 per cent. and 5 per cent. sugar. In going into her history he learned that she was abroad in 1904, living in the south of Germany. She was taken with intense pain and gave all the symptoms of an acute attack of peritonitis. After one or two weeks she was removed to a surgical clinic and a diagnosis was made of acute fat necrosis of the pancreas with the formation of an abscess. She was operated on and remained in the clinic three months before the fistula healed. She had sugar in her urine when she was admitted and had it when she left the clinic, but not so much. The woman was now well.

Dr. Erdmann said that while he did not mean to imply sugar was a factor in acute pancreatitis, at the same time he thought it might be a coincidence.

Officers Elected.—*President*, Walter Lester Carr; *First Vice-President*, H. Seymour Houghton; *Second Vice-President*, William Hallock Park; *Secretary*, John Van Doren Young; *Assistant Secretary*, J. Milton Mabbott; *Treasurer*, Charles H. Richardson.

Consideration and Action on the Constitution and By-Laws Presented by the Comitia Minora at the September Meeting with the Recommendation That They Be Substituted by the Society for the Present By-Laws.—The new constitution and by-laws were presented to the society, acted upon, and passed in accordance with the wishes of the Comitia Minora.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held February 20, 1906.

DR. WARREN COLEMAN IN THE CHAIR

A Case of Progressive Muscular Atrophy.—Dr. CHARLES E. NAMMACK presented this patient, a man, forty-nine years old, who entered the fourth medical division of Bellevue Hospital January 19, 1904. His family history was negative. He was a moderate user of alcohol up to six years ago. He had chewed tobacco since he was ten years old. He had gonorrhea once, ten years ago. He denied syphilis. The patient had been perfectly well up to October, 1903. One day he dislocated his shoulder. Two weeks later he was unable to hold a hammer in his right hand because he was unable to close firmly his thumb. During the next two weeks he noticed that his fingers became weaker and he was compelled to give up his work. During the next three months the fingers of the left hand became involved, and gradually the muscles of the forearm and shoulder became more or less weakened. He experienced no pain. He said he was perfectly well except for the weakness in the hands, forearm, and shoulder. The physical examination showed nothing except a valvular heart murmur. He presented the picture of Aran-Duchenne type of disease of spinal origin. There were presented the fibrillary twitchings characteristic of this disease. The electrical examination showed the reaction of degeneration. In this case were presented the four cardinal symptoms, viz., patient in middle life, marked atrophy of the muscles, reaction of degeneration, and fibrillary contractions. There was an absence of family history which one usually got in the dystrophies.

Progressive Muscular Dystrophy.—Dr. CHARLES E. NAMMACK presented two patients, brothers. The first patient was twenty years old, the youngest of thirteen children, six boys and seven girls. The calves of his legs became quite large and his playmates made fun of it. Although large, they were quite weak. When twelve years old the shoulder blades appeared large and there did not appear to be much flesh on the shoulder bones. When fifteen years old the muscles upon the back of the shoulder became very weak. During the last five years this condition progressed, and now he was unable to rise from the sitting to the upright position without placing his hands on his thighs. Lordosis was present. His manner of rising from the ground was quite typical of the disease. The brother was twenty-eight years old and he got up from the reclining position with more difficulty. He was a moderate user of beer, tobacco, tea, and coffee. He denied gonorrhea and syphilis. The first symptom he complained of was weakness in the legs. Then the muscles of the back became weak. There was a gradual increase in muscular weakness in the shoulders and arms. When twenty-three years old he could not climb into his wagon and was therefore compelled to give up his occupation. For two years his only trouble seemed to be the difficulty experienced in attempts to get up from a sitting to a standing position. As a boy he was large and bulky, and was possessed of unusual strength, a case of real hypertrophy. The manner of getting up was quite distinctive of the disease, although it was not at all pathognomonic. This patient had had typhoid fever one year ago, and during his confinement to bed the muscular disability seemed to make rapid progress.

Dr. Nammack pointed out the differential features betweeen progressive muscular atrophy and progressive muscular dystrophy, and stated that although these had hitherto been considered distinct diseases, certain recent writings made it probable that the distinction might not be so sharp as one believed. Still, as the question was not yet absolutely decided, it might be well to keep to the old divisions, especially as the types shown presented sharply-defined clinical entities, each with a fairly well determined anatomical basis. Dr. Nammack also wished to emphasize the necessity for keeping cases of dystrophy on their feet as long as possible, because the regular natural use of the weakened muscle far surpassed any other measure of treatment in arresting the progress of the disease. It was well known that confinement to bed by any acute intercurrent affection or surgical operation had a most disastrous effect, the dystrophic process seeming to speed when patients were not exercising in the upright posture. Beyond the systematic natural use of the muscles, other measures of treatment for this condition were of little use.

Dr. WILLIAM B. NOYES said that a more delicate classification, at least on pathological lines, could be made in these cases, according to the question of whether the spinal cord or the peripheral neurons were affected. Pseudohypertrophic paralysis had seemed to be a purely muscular disease and not really belonging to the list of organic nervous diseases. There was not wanting evidence to-day to associate it with pathological changes in the end organs of the nerves, though whether this preceded or followed the muscular changes it was hard to say. But there were cases of genuine pseudohypertrophic paralysis, where definite symptoms referable to the spinal cord were seen. One such case, with all the classical symptoms of this disease but with markedly increased knee jerks, was seen by Dr. Noyes within the last year, suggesting at least a secondary involvement of the cord. There was some definite progression in pseudohypertrophic paralysis, and it was not difficult to see the order of involvement of different portions of the muscular system that was sure to come in the course of time. In the progressive muscular atrophies depending on disease of the ganglion cells of the cord, the only thing that could be expected was that it would gradually spread as if by contiguity, and probably affect both sides of the cord rather than jump to a lower level. For instance, the cases that started with paralysis and atrophy of the muscles of one shoulder were quite as likely to affect the other shoulder as to run down the entire arm of the side originally affected. Yet there might be a progression, from the arm centers in the cord to the legs, without affecting any muscles between; the cause of this lay in some embryological factor. A somewhat better prognosis could be made in these chronic poliomyelitis cases, in that the progress of the disease might cease with the involvement of certain groups of muscles and not do any further damage. Pseudohypertrophic paralysis was steadily progressive, though in a case treated by the speaker the disease seemed to cease its progression for a number of years in response to massage and electrical treatment.

The Use of Hydrotherapy in the Treatment of the Insane.—Dr. GEORGE B. CAMPBELL presented this paper. He said that his object was to demonstrate in a general way the results attained by the use of hydrotherapy since the year 1898, when its use was first inaugurated by Dr. Dent in the Manhattan State Hospital. In the depressive phase of manic depressive insanity one frequently found slow and inefficient respiratory action, marked disturbance of the circulation, characterized by cold and clammy extremities, and inactivity of the cutaneous surfaces, with pronounced diminution of the body secretions. A similar condition was also observed in dementia præcox. In these

conditions the tonic and stimulating effect of the various douches, sprays, etc., under hydrostatic pressure, preceded by the hot-air cabinet, had been most extensively employed, and the results tended to show that the duration of the existing conditions was materially lessened, while in recoverable cases the duration of the psychosis had been materially shortened and the pathological conditions relieved at a much earlier date, thereby lessening the blow to the central nervous system. Realizing the importance of controlling motor excitement characterized by either anxious or exalted states, with their persistent insomnia, and being impressed by the distressing results of the prolonged use of sedatives, the prolonged tub bath, ranging in temperature from 99° to 100°, and even to 112°, was experimented with, and it was found that the longer the immersion the more prolonged was the effect. A miniature tub showing the entrance and exit of the water and an ingenious contrivance for controlling the velocity, was exhibited. The maximum duration of the bath was less than fourteen hours, though in one or two instances he had continued it for a period of six weeks. The physiological action of this form of hydrotherapy was still open to discussion. It was known, however, that the irritation caused by the warm water had a specific action on the cutaneous nerve terminations, and it undoubtedly caused an irritation of the peripheral ends which was summarily communicated to the vasomotor nerves, producing dilatation of the blood-vessels, and this meant acceleration of the circulation. This form of treatment was being used largely by the Germans as hypnotic, sedative, and eliminative. The application of water as a therapeutic agent required as much careful consideration of the indications and should be dispensed with the same degree of accuracy as our most potent drugs. A number of cases were cited showing the effects of this treatment, from which the author of the paper concluded that while he would not advise the abolishment of drugs in the treatment of the insane, he would emphasize the fact that in hydrotherapy we had a safe and effective hypnotic as well as a powerful eliminative, and that the intensity of the mental and motor manifestations was lessened, and the duration of the psychosis cut short by at least six to eight weeks. This had been demonstrated by comparison of similar cases treated by the ordinary hospital routine.

The Effect of Surgical Operations Upon the Insane.—Dr. LeRoy Broun read this paper. He spoke of the differences of opinion on this subject, as shown at the meeting of the British Medical Association held in Montreal in 1897 and the opinions held to-day. Within the last ten years the opinions of alienists and surgeons had reached a common plane. The alienists almost universally recognized the importance of rectifying and repairing pathological states existing among insane patients. The surgeon recognized that no operation should be performed except to rectify conditions disturbing the patient's physical well-being or endangering the life of the individual. An examination of the records of various insane hospitals showed that 75 per cent. of the female patients had some form of pelvic or abdominal disease, and these patients had a right to be relieved from any suffering entailed by these pathological conditions. The author confined his remarks to abdominal and pelvic surgery among women of the Manhattan State Hospital. During the three years ending October 1, 1903, 312 patients had been operated upon, which was less than 5 per cent. of the female population of the hospital during that time. Of this number, there had been 83 abdominal sections for various pelvic and abdominal diseases, and 229 operations of other character, chiefly plastic. Of the entire 312, 158 had been physically benefited in a marked degree. One hundred and thirty-one had been noticeably improved, but not to the extent of the previous class. Of the remaining patients, six had died, three from natural causes and three from causes attributable to the operation. Many of those operated upon had been subjects of mental disease, giving little hope for a favorable outcome. Of the entire number, 52 were discharged as mentally recovered. Of these, 23 showed more rapid mental improvement under the recognized hospital treatment after the operation had been performed than before. The character of mental alienation present in these 23 cases was: Melancholia, chronic, 7 cases; melancholia, acute, 7 cases, mania, acute, 5 cases; dementia, primary, 4 cases. He thought the efforts of some to benefit patients by producing a premature menopause had done much harm. In his entire range of operations on the insane there had been no instance in which a patient's mental condition had been aggravated by a proper surgical procedure. Of the 83 abdominal sections for various conditions, 12 per cent. were among those discharged as mentally cured. Among these 9 patients it was necessary to remove both adnexa in only two instances. These operations were two myomectomies, with suspension of the uterus, three suspensions of the uterus for adherent uterus, two supravaginal hysterectomies, one ovarian cyst, and one Bassini operation for hernia.

Of the 229 minor operations, 14 patients were among those discharged as cured, or about 6 per cent. He did not attribute the cures to other causes than the improved physical condition of the patients after operation. It was of the utmost importance that the physical health of the patient should be brought to its highest state of perfection at as early a period as was possible after the mental breakdown. He thought the following facts were well established: (1) If the operation had been properly done and the patient had not been subjected to uncalled-for castration, the mental condition was never aggravated. (2) Under the stimulus of the improved somatic state, some patients showed greater mental changes under the moral and therapeutic care than was shown before such relief was given. (3) At times this improved mental state continued to one of recovery. The primary object of surgical operations upon the insane should be to improve the physical status of the patient.

Operative Surgery upon the Insane.—Dr. Warren S. Bickham read this paper. He said that in our present state of knowledge it was never wise to operate to cure insanity, but we should operate to relieve patients of accompanying physical conditions, the exact relation of which to the mental state being, at present, not within our power to fully know. The outcome of such a course was that the physical ailment was cured in the great majority of cases and the mental ailment in a certain percentage of cases. Even where there was no mental improvement noted, the patient was generally made more comfortable and useful by the operation. One should operate upon the insane for the same conditions as for the non-insane. The best method of obtaining the direct value or the reverse of operations on the insane would be to select certain groups of insanities in the larger institutions, operate upon the demonstrable lesions in half the number and carry out a non-operative course in the other half, and then compare the mental condition of the two groups after a reasonable length of time. At present many collections of statistics were untrustworthy and misleading. The best outlook for improvement following operation was in those cases where the operations restored or greatly improved the general health. A tangible physical condition might indirectly predispose to insanity by lowering the bodily health of the individual, and in such cases operative interference was especially indicated. Improvement and sometimes even cure seemed to be the result of the shock of the operation. Such accidents could not be considered the result of intelligent effort. So far as operating upon the brain itself was concerned, an operation should be undertaken to remove a demonstrable lesion, especially where localized phenomena existed and where the operation was performed before the cells involved had been injured beyond recovery, benefit was to be expected. Contraindications to operating upon the insane were two: First, the possibility, inherent in all operations, that the patient might

not survive the operation itself; and, second, as to whether there was likelihood of increasing the degree of insanity through the act of operating. Authentic cases where such an accident had occurred were exceedingly rare. He spoke of the non-fitness of the majority of surgeons to do their own localizing, and said that for the highest development of neurology, in the broadest sense, some neurologists should become surgeons and some surgeons should be better neurologists. His personal work in operating upon the insane had as yet been too limited to be of very great value. Of twenty insane patients operated upon for the correction of demonstrable lesions of general surgery, one died as a result of anesthesia pneumonia and suppurative meningitis, but none of the others were made worse by the operations. As to their insanity, the physical conditions of all were believed to have been bettered, and the cure of the insanity of two was considered to have followed operation, whether causatively or coincidently might be inferred.

Dr. William H. Thomson said that there was no one measure that would more surely make a hyperacid urine alkaline as prolonged immersion in tepid water; in fact, all the acid secretions of the body were rendered alkaline. The Romans knew this, and, therefore, they forbade anyone partaking of a heavy meal before taking a bath. A good deal of the benefit from taking mineral baths was not due to the mineral ingredients, for the skin would not absorb the minerals, but the nerves were powerfully affected, especially in the direction of sedation. To this fact was due the muscular relaxation, better brought about by a warm water douche than anything else. He recalled a case of universal contractions with persistent flexures which followed an attack of spinal meningitis. The patient begged not to be touched because of the suffering it entailed. The fingers were drawn into the palms, causing ulcers; ulcers also appeared upon the knees and buttocks; in fact, anywhere that the flexed parts touched other parts. It was said that the patient could live but a short time. Dr. Thomson gave a favorable prognosis, and had the patient douched three times a day with hot water, one-half to one hour at each sitting, with the result that the patient was soon able to walk out of the hospital with the contracted muscles relaxed. This was due to the suspension of the surface irritation, which acted upon the motor nerves, causing muscular contractions. Warm baths reduced the acidity of the secretions, the hyperacidity of the blood, and were also a powerful agent in their sedative effect upon the peripheral nerves; therefore they had a practical application of this method of the highest value in the treatment of excitable conditions of melancholia or maniacal conditions in the treatment of the insane.

Dr. Brooks H. Wells said that he could discuss only the psychical effect caused by surgical operations on the generative organs of women. He did not believe that surgical operations caused insanity, except possibly in rare instances, where a predisposition existed and where both ovaries were removed. Neurasthenic or hysterical psychoses might be greatly intensified by any operative procedure. On the other hand, he did not believe that insanity was ever caused by a surgical operation *per se*, yet he emphasized the fact that anything which tended to improve the patient's bodily condition might aid in curing any psychosis from which she suffered. Therefore operations should be done in the insane as in the sane, when such operation would remove physical pain or disability. In general, the milder and more recent the insanity, the greater was the indication for operation. In certain cases of acute insanity caused by sepsis, any operation which might remove the infection was urgently indicated, not only to benefit the physical condition, but the mental as well.

Dr. Achilles Rose said that the warm bath surrounded the surface of the body with an equal temperate medium, doing away with the fluctuation of the loss of heat, and acted soothingly. The thermic irritation of the peripheral nerve endings, while it lessened the sensation of pain, excited at the same time by way of reflex action, especially in the muscle, an increased metabolism. The fatigue was caused by more than normal accumulation of the products of this function. To oxidize and eliminate these products, a certain amount of metabolism was required. The specific effect of the warm baths was to afford immediate facility for oxidation. The changes of the physical and chemical condition of tissues, the augmentation of the organic function, the acceleration of the blood circulation, the dilatation of the blood-vessels, all depended on the specific action of the continuous warm bath on innervation. The effect produced by the thermal irritation of the extremities of the nerves was manifested primarily at the point of contact and along the centripetal organ itself, and was also conveyed from there by the centrifugal motor tracts. In general the products of inflammation and infection were taken up by the circulation and eliminated more extensively and quicker under the influence of the warm bath; at least such was the case in local affections, as, for instance, in arthritis and in erysipelas of the extremities; it also applied to cerebrospinal meningitis. He said the theory that had been prevailing that functional work was taken off the internal organs when there was a superabundant flow of blood to the skin, was erroneous. It had been proven that hyperemia produced by heated steam spread to the lower strata, and from this it followed that dilatation of the main vessels was not necessarily followed by contraction of the visceral vessels. It had been assumed that an increased blood supply to any part of the body would be followed by a diminution in another part. In reality, however, the quantity of blood was constantly changing and the regulation took place in the capillaries. The visceral vessels were dilated in really the same way as the skin vessels, and physiological observation had shown that, as the vessels became dilated, the blood flowed more rapidly. Physiology did not furnish a single instance in which the speed of the circulation decreased with simultaneous dilatation of the vessels. In the vascular system he said there were two forces, the pressure and the suction, supporting each other. The heart was not a mere pressure pump; it was as well a suction pump. The suction or siphon action not only played an important rôle in the cardiac function, but everywhere else in the body where vascular dilatation created a vacuum; the power of the siphon action caused an acceleration in the flow of blood as the vessels became dilated. Dr. Rose believed there was a great future for the employment of the continuous bath in all diseases in which increased metabolism was desirable as the principal condition of a cure.

Dr. George W. Jarman said that he was not so positive as some that people did not go insane from operations, and he referred to two patients in his own practice who went insane following a surgical procedure, and undoubtedly owing to the operation. One had a rapidly-growing ovarian tumor on both sides, both tumors being very large. He felt certain that the patient was sane. He operated, removing both ovaries; there was no healthy tissue to be noted in either ovary. Within six months this patient went completely insane; whether *post hoc* or *propter hoc*, he was unable to say. The same result followed in another case, where he did a complete hysterectomy for a large bleeding fibroid tumor. Here were two cases that came under his own direct observation in which insanity followed operation, and he said he was positive that he had seen two others operated upon by other gynecologists with the same result. This condition seemed to follow only where both ovaries were removed. He believed the deductions drawn by Dr. LeRoy Broun to be correct. Insane women require operation for the same reason that the sane did.

Dr. LeRoy Broun closed the discussion. He referred to a paper published in 1893, which gave valuable statistics and showed definitely that in the previous ten years there were only twenty-five patients who had been admitted to the hospitals in America and in Canada who claimed to have become insane subsequent to operations. This was indeed a remarkably small number.

SECTION ON MEDICINE.

Stated Meeting, Held May 22, 1906.

DR. WARREN COLEMAN IN THE CHAIR.

A Case of Infection with the Bacillus of the Intermediate Group.—Dr. CHARLES NORRIS and Dr. GORDON LINDSAY reported this case. A brief review was presented of the cases of infection with members of this group since the time that Bollinger first called attention to the gastro-intestinal symptoms which follow the ingestion of unsound meat, and the demonstration by Gaertner of the etiological connection of the *B. enteritidis* with an epidemic which occurred in Frankenhausen. The patient was admitted October 12, 1905, to the service of Dr. Nammack, at Bellevue Hospital, to whom the authors were indebted for the clinical history. Two weeks before admission to the hospital the patient had a chill, followed by fever and sweating, and immediately went to bed. Chilly feelings and fever were present every evening. She complained of abdominal pain, and had three or four watery diarrheal movements every day. There was a heavy brownish coat on the tongue. There was tenderness over the hepatic and splenic regions, and slight tympanites. The urine contained albumin and numerous hyaline granular casts. Diazo reaction was negative. Temperature 103° to 105°. Patient died within twenty-four hours of admission. Autopsy was performed twenty-four hours after death by Coroner's Physician O. H. Schultze. The anatomical diagnosis was: Diphtheritic enteritis, localized phlegmonous gastritis, localized suppurative peritonitis, extreme congestion of suprarenals, hemorrhagic infarction of lungs, fibrous pleurisy right lung, and hemorrhagic phlegmons of the subcutaneous tissue of legs. At the cardia of the stomach there was an area of infiltration and thickening, measuring 6 cm. in diameter. Wall of the stomach at this point was greatly thickened (15 to 20 mm.). The submucosa, muscular, and serous coats were edematous and infiltrated with pus. Peritoneal sac contained a small amount of free pus. No ulceration of the mucosa over the area of infiltration was present. Spleen was congested and large. Capsule was thickened, and covered with a thin layer of pus. Liver was large and congested. Kidneys showed a slight parenchymatous degeneration. The suprarenals were extremely large and hemorrhagic. The tissues behind the right suprarenal were hemorrhagic. The lesions in the small intestine began about three and one-half feet from the duodenum. The valvulæ conniventes were intensely swollen and covered by a greenish slough. The lower part of the ileum showed numerous areas of intense congestion, covered by greenish slough, which on removal left an ulcerated surface. Peyer's patches were not affected. The lymph nodes at the hilus of the mesentery were swollen and edematous. Cultures were made from the spleen, liver, gall-bladder, and the infiltrated area of the stomach. A bacillus of the intermediate group was obtained in pure culture from these locations, and a mouse inoculated subcutaneously with the intestinal contents died over night, and the same bacillus was recovered in pure culture from the heart blood.

A second case of infection with a bacillus of the same group was presented. The patient, except for chronic tonsillitis, had always enjoyed good health. On June 17, 1901, illness was ushered in by vomiting, malaise, and prostration. She entered the service of Dr. Wm. H. Thomson of Roosevelt Hospital, to whom they were indebted for the history and the privilege of reporting the case. Death occurred two days later, five days after the onset of the first symptoms. The vomiting was severe and continuous, marked by great thirst, fever, prostration, and delirium. Frequent bright, greenish stools were passed, and severe abdominal pains were experienced during the last day. The diagnosis was acute gastritis or gastroenteritis, with toxemia. Autopsy was made thirteen hours after death. The lungs were hyperemic and dry, without areas of consolidation. The bronchi were congested. Heart muscle was slightly pale. The intestinal serosa in places was dull. No fluid in the peritoneal cavity. Ascending colon was firmly contracted, and the rectum empty. Spleen was small, firm, and light red in color. Splenic follicles slightly enlarged. Suprarenals appeared normal. Parenchymatous degeneration of the kidneys. Stomach was almost empty, and free from odor. Slight injection of several of the rugæ. Stomach was otherwise normal in appearance; likewise the duodenum and pancreas. Gall-bladder contained greenish bile, and one small calculus. The liver was slightly enlarged, brownish-red in color, and cloudy on section. Mesenteric lymph nodes were enlarged, succulent, and hyperemic, and presented many hemorrhagic areas in their central portions. Peyer's patches of the lower ileum were somewhat enlarged and raised, and in places hemorrhagic. Otherwise the small and large intestines were normal. Anatomical diagnosis: Acute parenchymatous nephritis; acute hyperplasia of mesenteric lymph nodes, and of the lymphatic tissues of the intestines, due to an acute general infection. Cultures were made from the liver, spleen, kidneys, and mesenteric lymph nodes, upon Hiss' plate medium, gelatin, and glycerin-agar. From these locations a practically pure culture of a bacillus of the intermediate group was obtained. No typhoid bacilli were recovered. A few colonies of the colon bacillus were recovered from the spleen and kidney plates. Short bacilli which decolorized by Gram's stain were seen in the cover-slip preparations made from the organs cultivated. The blood-serum of the heart blood taken at autopsy did not agglutinate the bacillus isolated. The bacillus was found to correspond in every particular to *B. psittacosis* of Nocard, and to the "Seemann" paratyphoid bacillus of Schottmüller. The clinical course of the case, an acute gastroenteritis of unusual severity, differed widely from those which have been described under the name of paratyphoid fever. No history of the ingestion of unsound meat or other source of infection was elicited from the family in which the girl was living, and no other case of illness had been observed in the apartment. The difficulty of tracing the source of infection in large cities was pointed out, and they believed that the milk derived from cows suffering either from infected breasts or from gastrointestinal disturbances was responsible for many cases of this kind of infection. The two cases that they presented they considered could not be consistently grouped under the head of paratyphoid fever, since the cases of infection with a bacillus of this group had presented clinical pictures which could not be harmonized into anything like a distinct group of clinical symptoms or of histological appearance such as existed in infections caused by the typhoid bacillus. They believed that the opinion of Wells and Scott, that fatal paratyphoid cases were rarities, rather than overlooked through imperfect bacteriological studies, was not justified, the statement being true only of those cases of infection with the intermediate group, which ran a course similar to typhoid fever. The authors preferred to call the cases reported infections or septicemias due to bacilli of the intermediate group of intestinal origin.

Dr. WARREN COLEMAN protested against making a diagnosis, basing it upon bacteriological grounds. Very few of these cases are observed in the laboratory; it seemed to him that the classification should be based from a clinical standpoint and not from the bacteriological.

Instrument for Measuring the Coagulability of the Blood.—Dr. HARLOW BROOKS presented a modification of Biffi's instrument for measuring the coagulability of the blood.

A Case of Melanosarcoma.—Dr. C. N. B. CAMAC and Dr. M. I. SCHOENBERG presented this clinical report.

A Case of Toxemia of Pregnancy.—Dr. C. N. B. CAMAC reported this case.

The Relation of Serum Treatment to the Etiology of

Graves' Disease.—Dr. S. P. Beebe read this paper. He called attention to the fact that most attempts to cure Graves' disease by means of serum therapy had been based upon the assumption that the chief function of the thyroid secretion was to neutralize a toxin which arose during the course of metabolism. The results from these efforts had not, as a whole, been favorable. The basis for the serum which he had prepared was the hypersecretion theory of the cause of exophthalmic goiter. He outlined the arguments which he thought could not be reconciled to any other view than that of hyperactivity of the thyroid gland as the most important factor in the etiology of the disease. The results of experiments agreed with the hypothesis, and the following conclusions were drawn: (1) Highly specific cytolytic serum could be developed by the injection of liver nucleoproteids. Serum developed by the injection of liver nucleoproteids acted only on the liver; that developed from kidney nucleoproteids acted only on the kidney. (2) The serum was hemolytic and hemagglutinative in high concentration in test tube experiments, but in the concentration in which it was given in the animal experiments such properties were not exhibited. (3) A latent period of somewhat varying length was found to elapse between the administration of the serum and the onset of symptoms. (4) The animals in which the serum was developed, rabbits, gave serum of widely varying degrees of potency under the same treatment. The dogs to which the serum was given showed some variation in their reaction to the treatment. The same animal species had to serve as the source of the nucleoproteids as was later to be subjected to the injections of the cytolytic serum. Although this work with cytolysins prepared from dog tissues was the basis for the later preparations of an antithyroid serum, the method of developing the latter was not in all respects similar to the former. In order to neutralize the toxin, it was necessary to include thyreoglobulin in the injection mixture, and to inhibit glandular activity, and to act as a cytolytic factor the nucleoproteids were included. From the toxin we should develop an antitoxin, and reasoning from the results in experiments with dogs it seemed possible to develop thyreolysin from the nucleoproteids. A serum prepared in this manner was quite different in principle and properties from those properties obtained from thyroidectomized animals. In the preparation of proteids, normal human glands obtained at autopsy were ground to a fine hash by a special machine. From six to eight times the volume of 0.8 per cent. salt solution were added, and the whole thoroughly shaken and allowed to extract for twelve hours in the refrigerator, chloroform and thymol being added to prevent bacterial growth. At the end of this period coarser particles were removed by straining through gauze; the filtrate was centrifuged, and finally filtered to remove the finest particles. The clear filtrate contained three classes of proteids, namely, nucleoproteids, globulins, and albumins, the first two of which were to be used. Nucleoproteids were precipitated by the use of acetic acid to a frank acid reaction, using litmus as an indicator. He found a very marked difference between normal and Graves' glands in respect to this precipitation. Normal glands did not give a definite flocculent precipitate. The normal gland contained a very small proportion of nuclear material and a relatively large quantity of colloid. The precipitate was scant if the glands were not in a perfectly fresh condition. These proteids were twice redissolved in alkaline sodium chloride solution, and reprecipitated by acetic acid and ammonium sulphate solution. The proteids were then carefully removed and dialyzed in a parchment tube for four days, with the addition of thymol as an antiseptic. The contents of the dialysis sack were made feebly alkaline with sodium carbonate, and the solution, containing the desired proteids, kept in the refrigerator. Before injection the solution was filtered. In other cases he had tried to determine how a serum made from the nucleoproteids alone would compare with that made by including the globulins. If the injected material was acid in reaction or if the reaction was too strongly alkaline, a fatal peritonitis was likely to result. The animals used for developing the serum were rabbits, dogs, and sheep. For some reason dogs had not yielded an efficient serum and their use had been discontinued. It was not possible to predict the activity of a serum which any given animal might produce. Serum had been obtained from a large number of rabbits, both for the thyroid experiments and also in continuation of the work on cytotoxins, and it was possible to say that the best serum could be produced in large buck Belgian hares. The animals should be full-grown young adults, weighing from six to eight pounds, and should be well fed and cared for throughout the immunization period. It sometimes happened that an animal that seemed to be in prime physical condition failed to produce an active serum Injections were made into the peritoneal cavity. The proteid from ten grams of thyroid was employed for an initial dose in a six-pound rabbit, and a subsequent dose determined by a loss of weight. In regard to the properties of the serum, it had been found that the more active the agglutinating powers, the more marked the local and general reaction following injection. In order to have comparable conditions a definite method had been followed in making agglutination tests. The serum was highly specific in its agglutinating power. In regard to the hemolytic properties, he had no satisfactory evidence that the results of test-tube experiments applied in the body, and it was quite conceivable that a serum might be hemolytic *in vivo* in much more dilute concentrations than were required *in vitro*. Clinically, he had found that the serum treatment generally caused an increase in the percentage of hemoglobin and number of erythrocytes. Such a result might be due to the general improvement in health. As to the therapeutic effect, he had noticed a striking improvement in all symptoms within forty-eight hours. Cases which showed such behavior were generally those having an acute development, with a soft thyroid gland. Only a small proportion of the cases showed the striking immediate improvement just suggested. The majority showed gradual slow improvement, which though positive and undoubted, did not afford such convincing evidence of antitoxic action. The majority of cases treated had been of the chronic type. In these cases the gland was more cellular, and presumably the cytotoxic element in the serum could not act with sufficient vigor to cause immediate and rapid diminution in the gland. More rapid destruction might possibly result in a dangerous acute toxemia from the decomposition products of the gland. More recent experiments had demonstrated that it was possible to develop a serum of high therapeutic efficiency from proteids of the normal gland. If we found that the serum from the normal gland was quite inefficient, it would indicate the presence of a special toxin in the pathological gland. Chemical investigation had not revealed any special toxin. The most active serum which he had thus far developed had come from the proteids of certain glands removed at operations. Its activity had been expressed in its agglutinin reaction, local and constitutional reactions on injection, and its therapeutic effect. He accounted for this by the fact that the glands removed at operation were fresh. The differences in reaction which patients showed to the same serum, as well as the differences in the quality of the serum, had to be taken into consideration. If the hypothesis regarding the antitoxic and cytotoxic property, and their dependence upon the injection of thyreoglobulin and nucleoproteid respectively, was correct, we should find it advisable to vary the activity of the serum in respect to these two factors, in order to meet the indications in the various types of cases. Experiments of this sort were under way. When all conditions were considered, he believed it fair to conclude that the serum was an agent of considerable value in the medical treatment of Basedow's disease. It had been used in all manner of cases in which it was possible to make a diagnosis, and in some

cases where the diagnosis was doubtful. Only a comparatively small percentage of these had been of recent development. A small percentage of trials had resulted in failure, a much larger number in improvement, while an encouraging number had been cured.

Dr. Harlow Brooks said he was not able to offer any definite personal opinions regarding the etiology of Graves' disease. He said he had made six autopsies on those who had died of this disease, and he had studied them most carefully, and so many changes were found in the cardiovascular system and kidneys that he doubted if one was justified, from the post-mortem findings, in offering any conclusions as to the etiological factor concerned in the production of the disease. He had two cases under the serum treatment, which he briefly outlined. One case was apparently cured in the early stages of the disease. The second case was now in the third year of the disease, was apparently somewhat benefited by the treatment, but was not yet cured.

Dr. C. N. B. Namac said that the histological findings in the thyroid gland would be of great interest. For instance, the finding of this colloid-like material in the normal gland, which was practically missing in the diseased gland, would have a suggestion of not overproduction, but of the failure of production. This colloid-like material had been proven to be coagulated serum. The contents of the gland had been practically exhausted. With thymus extract, too, in these cases, improvement had taken place. He asked regarding the correlation between the thyroid, the parathyroid, and the thymus glands. The ox thyroid had some of the parathyroid mixed in, which he believed accounted for the benefit received.

Dr. Richard Weil said that the etiology of Graves' disease was a very complex thing, presenting so many variations. We could hardly expect to get a solution of the question of etiology from the action of therapeutic measures. Two cases had been observed over a course of seven weeks, receiving an energetic course of treatment with the serum, and these cases he reported in detail.

Dr. S. J. Meltzer said that Dr. Beebe claimed merits of the serum treatment based upon clinical evidences. Dr. Weil had told of two cases where the pathological serum was used without effect. Dr. Brooks had told of one case where the normal serum was used without much effect, and Dr. Rogers had made the statement that in three cases where the normal serum was used dangerous symptoms were presented. He said that anyone who had been in practice for a number of years knew how much reliability could be placed on the therapeutic measures employed in a disease like Graves' disease. In the literature could be found many cases, as Dr. Camac mentioned, in which the use of the thymus gland produced benefit. Dr. Meltzer recalled a case in which a patient was advised to go to the slaughter-house and take thyroids; by mistake she took thymus glands, with apparent benefit. Dr. Meltzer said that if Dr. Beebe relied upon the clinical evidence, he had no evidence at all. It certainly was a great era in medicine when one, two, or three injections of a serum could cure a disease which had lasted for ten, fifteen, or twenty years. Therapeutics to-day could not be taken as scientific facts, and if Dr. Beebe had any scientific basis for his conclusions regarding the advantageous use of the serum, he did not discuss it. Eight out of forty-five cases were reported cured at the recent meeting of the Association of American Physicians at Washington; but the clinical evidence showed they were only a short time cured.

Dr. S. P. Beebe said that in the beginning of Graves' disease nothing more than an enlarged gland was found, with the same conditions histologically as in a normal gland; but as the process went on there was a decrease in the colloid material; in the beginning there was an increase of it. Cases that had existed for eight or nine years had very little colloid in the cells of the gland. The thymus treatment to him was interesting, and he believed that in Graves' disease the thymus was involved in most cases. Many striking cases of improvement in Graves' disease had been reported. Of sixty cases reported, 90 per cent. showed improvement; the precise percentage of those cured he did not know. Dr. Meltzer had stated that the disease could be improved with almost anything; that was not the universal experience of those who had used the serum. With regard to suggestion, he said that he had repeatedly given Dr. Rogers a normal serum without Dr. Rogers knowing it, and he got no results whatever and he had wondered what the trouble was. The normal serum would give no results.

The Treatment of Purpuric Conditions and Hemophilia.—Dr. J. W. Coe said that in view of the cases reported, it seemed that the calcium, or probably the magnesium salts as well, offered the best hope of relief of any therapeutic measures thus far advised. There was theoretically some danger of causing thrombi formation, but this was slight if we determined with each case the minimum dose necessary to make the patient comfortable. Twenty or forty grains of the lactate once or twice a week was usually sufficient for the chronic cases. The large doses given a patient with acute hemorrhagic purpura was evidence of the harmlessness of the drug when such doses were necessary. The lactate was more easily absorbed than the chloride of calcium, and the taste was much more agreeable. All patients were directed to drink from one to two quarts of milk a day, and some of the improvement probably resulted from this, for Wright had shown that this accelerated coagulation. Summarizing the coagulation on the cases cited, it was seen that in two of the five it was decidedly above normal, in two others a high normal, and in the fifth a low normal. In all the cases the blood must have had a high content of calcium, so that the results in these experiments accorded with those of Wright and Knapp, who demonstrated by chemical means that a blood which contained a small amount of calcium was not always less coagulable, and also that a blood containing much lime salts was not necessarily more coagulable than usual. It had been claimed that the continued administration of calcium chloride was not effectual in keeping up an increased coagulability of the blood, but served to lengthen the time. Whether the effect of the lactate was different in this respect, or the improvement was due in chronic cases to the fact that they had taken the minimal effective dose, could not be said, but concerning the improvement there could be no doubt. In no case had the coagulation time been lengthened by the lactate. Two of his patients, who were intelligent, could, by carefully regulating the lactate, keep themselves infinitely more comfortable than for years. In the course of these investigations many blood investigations were made. The one constant feature was the small number of blood plates. This fact had been observed before, but he believed that sufficient importance had not been attached to it. By following such bloods from day to day, one could not help thinking that there was a close relationship between the fewness of the plates and the liability to bleed. In one case the plates suddenly disappearing, it was suggested fully forty-eight hours before it began that bleeding was about to occur. In two other cases blood taken the same day on which had occurred the most severe attack of epistaxis for months, a total absence of blood plates was noted, when they had previously been present, but much below normal. After the bleeding arsenic was given, with the idea of stimulating the hemogenetic organs. The fact that the blood plates rapidly increased in number after beginning the arsenic, argued in favor of the bone marrow as the seat of origin. As a means of counting the plates Pratt's method was probably the best. This consisted in diluting the blood with a 2 per cent. solution of sodium metaphosphate and obtaining the ratio of plates to the red cells. The actual enumeration was probably more accurate, but the technique was arduous and could not be applied in many cases. Heretofore nearly all observers had agreed that little concerning the plates could be learned from a stained specimen, but it

must be remembered that such investigations were made before the use of the dyes was common. He believed that by making evenly smeared thin specimens and using a stain like Wright's, Leishmann's, or the Jenner of Hastings, fully as good an idea of the plates could be obtained as by counting them. Secondary anemias always showed a marked increase in the plates. In all the cases reported by the writer there was at some time distinct anemia, but the plates were constantly reduced. Another point of difference between the two varieties of anemia was that a leucocytosis was usual with secondary anemias of purpura. Keeping these points in mind, one should always be able to differentiate between a bleeding from a hemorrhagic diathesis and a hemorrhage from other causes.

Dr. W. J. Simpson said he had used lactate of calcium to a considerable extent. He had come to the conclusion that as an hemostatic the chloride of calcium was very inefficient. Since beginning the use of the lactate he had had better results. He said he had used it in nasal and pharyngeal operations with benefit. In nose and throat work he had used lactate of calcium first, to prevent hemorrhage during operations, and, secondly, to guard against secondary hemorrhage. The effects of this agent had been excellent.

Dr. T. W. Hastings and Dr. S. J. Meltzer discussed the paper.

Are Preservatives in Food Injurious to Health?—Dr. E. E. Smith read this paper. He reviewed the causes which made food preservatives a necessity, and their history from the earliest times. Foremost among the questions for sanitarians to consider was the effect of the various food preservatives upon the health of those who consumed the food. The diversity of opinions of different authorities at the present time bespoke the difficulties and complexities of the question. Too often personal considerations entered into and interfered with an unbiased judgment on the question. Thus, even the physician whose practice included men with commercial interests was apt to look at things from their point of view. The best that we could do was to establish separate facts by individual investigators, verified by a sufficient number of investigators, and submit these facts to a final conclusive body of men so organized that personal interests would be neutralized. We could not as yet answer the food question, but we might contemplate how we should approach the consideration of the subject. We might view the subject in three divisions: (1) Are food preservatives themselves directly injurious to health? (2) May their presence in food be indirectly a cause of injurious conditions of food? (3) Is it expedient to permit their use in food? He dealt only with the first of these questions. The fact that we had no certain knowledge of the injuriousness of these preservatives from experience was evidence that the degree of injury was not such as to characterize these substances as poisonous. As to whether they produced any minor degree of injury to health such as would be designated as unwholesome, would have to be decided by the results of experiments. There was no doubt but that substances used as food preservatives could be used in such quantities as would be capable of producing injury to health. In the experimental study of this question we would naturally first determine the character of the injurious action of the excessive amounts of the substance in question, and next we would determine the minimum amount capable of giving rise to any injurious action, and finally we would determine whether the amounts used were sufficiently removed for safety from the minimum injurious quantity to justify such use.

Dr. Geo. B. Wallace said that he differed from Dr. Smith so far as the experimental work was concerned. A considerable amount of work had been done by some German investigator with boracic acid, and the conclusion was reached that there was a tendency for boracic acid to bring about gastric disturbances and diminished absorption of fat and proteid from the intestines. If boracic acid was used for months the results might be harmful; but where the experiment period lasted but a short time there were no deleterious effects.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Schott Methods of the Treatment of Chronic Diseases of the Heart. By W. Bezly Thorne, M.D., M.R.C.P. Fifth Edition. 8vo, 140 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $2.00. net.

Diet and Food Considered in Relation to Strength and Power of Endurance, Training and Athletics. By Alexander Haig, M.A., M.D., F.R.C.P. Sixth Edition. 12mo, 139 pages, illustrated muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.00, net.

The Extra Pharmacopœia. By W. H. Martindale, Ph.D., F.C.S., and W. W. Westcott, M.B.-Lond, D.P.H. Twelfth Edition. 32mo, 1,045 pages, leather. H. K Lewis, London, Eng. Price, 10s., net.

Operative Gynecology. By Howard A. Kelly, A.B., M.D., etc. Second Edition, Revised and Enlarged. Vol. I, 4to, 600 pages, Vol. II, 4to, 656 pages, illustrated, muslin. D. Appleton & Co., New York.

A Text-Book of Human Physiology. By Dr. Robert Tigerstedt. Translated from the Third German Edition and Edited by John R. Muriln, A.M., Ph.D. 8vo, 751 pages, illustrated, muslin. D. Appleton & Co., New York.

Christ Among the Cattle. By Frederic Rowland Marvin. Fourth Edition Revised and Corrected. 12mo, 58 pages, muslin. Pafraets Book Co., Troy, N. Y.

General Medicine (Vol. VI. Practical Medicine Series). Edited by Frank Billings, M.S., M.D., and J. H. Salisbury, M.D. 12mo, 363 pages, muslin. The Year Book Publishers, Chicago. Price, $1.25.

A Manual of Otology. By Gorham Bacon, A.B., M.D. Fourth Edition, revised and enlarged. 8vo, 485 pages, illustrated, muslin. Lea Brothers & Co., New York.

Progressive Medicine. Edited by Hobart Amory Hare, M.D., and H. R. M. Landis, M.D. Vol. III, September, 1906. 8vo, 298 pages, illustrated, paper. Lea Brothers & Co., Philadelphia and New York.

Chemistry, General, Medical, and Pharmaceutical. By John Attfield, F.R.S., Nineteenth Edition. 8vo, 756 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia and New York.

Eating to Live. By John J. Black, M.D. 12mo, 408 pages, muslin. J. B. Lippincott Co., Philadelphia.

Malattie dell'Orecchio, Naso e della Gola (Oto-Rino-Laringo-Iatriaq. By Dr. Tommaso Mancioli. 32mo, 540 pages, illustrated, muslin. Ulrico Hoepli, Milan. Price, L. 5.50

Essays in Pastoral Medicine. By Austin O'Malley, M.D., and James J. Walsh, M.D. 8vo, 363 pages, muslin. Longmans, Green & Co., New York. Price, $2.50 net.

Transactions of the Southern Surgical and Gynecological Association. Vol. XVIII. Edited by W. D. Haggard, M.D. 8vo, 456 pages, illustrated, muslin. Published by the Association.

L'Ame et le Systeme Nerveux Hygiene et Pathologie. By Auguste Forel. 8vo, 334 pages, illustrated, paper. G. Steinheil, Editeur, Paris. Price, 5 francs.

L'Autointoxication Intestinale. By Dr. A. Combe. 8vo, 568 pages, illustrated, paper. J. B. Baillière et Fils. Paris. Price, 12 francs.

[illegible] By Dr. Paul Maisonneuve. 8vo, 79 pages, paper. G. Steinheil, Editeur, Paris. Price, 2 fr., 50 c.

Tuberkulose-Arbeiten aus dem Kaiserlichen Gesundheitsamte. 5 Heft., 4to, 295 pages, illustrated, paper. Julius Springer, Berlin.

Procès-Verbaux, Rapports et Discussions du Premier Congrès de la Société Internationale de Chirurgie. Publiés par le Dr. A. Depage, Secrétaire général du congrès. Bruxelles, Hayez, Imprimeur des Académies Royales de Belgique, 1906.

State Medical Licensing Boards.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	Dec.	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	January	7
Arkansas*	J. P. Runyan, Little Rock	Little Rock	January	7
California	Chas. L. Tisdale, Alameda	San Francisco	Dec.	18
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	January	1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov.	13
Delaware	P. W. Tomlinson, Wilmington	Dover	Dec.	11
Dis. of Col'bia	W. C. Woodward, Washington	Washington	January	10
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta	April	—
Idaho	J. L. Conant, Jr., Genesee	Lewiston	April	2
Illinois	J. A. Egan, Springfield	Chicago	January	—
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May	28
Iowa	J. F. Kennedy, Des Moines	Des Moines	Dec.	11
Kansas	T. E. Raines, Concordia	Topeka	February	12
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	23
Louisiana	F. A. La Rue, 211 Camp St., New Orleans	New Orleans	May	9
Maine	Wm. J. Maybury, Saco	Portland	Nov.	13
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec.	12
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Nov.	13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June	11
Minnesota	O. E. Linjer, 24 South Fourth Street, Minneapolis	St. Paul	January	7
Mississippi	J. F. Hunter, Jackson	Jackson	May	14
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	Nov.	26
Montana*	Wm. C. Riddell, Helena	Helena	April	—
Nebraska	Geo. H. Brash, Beatrice	Lincoln	Nov.	7

Wisconsin	J. V. Stevens, Jefferson	Milwaukee	January	8
Wyoming	S. B. Miller, Laramie	Cheyenne	Dec.	5

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Arkansas.—Examinations in this State are held four times a year, on the second Tuesday in January, April, July, and October. Anyone entering the State and desiring to practise, prior to the time for a regular examination, may apply to any member of the board for an examination, and, if he passes this satisfactorily, can obtain a temporary permit to practise until the next meeting of the board. He must then pass the regular examination and obtain a certificate in the ordinary way.

Missouri.—The method of dealing with the old practitioner, in allowing 5 per cent. on examination for each five years of actual practice, initiated by the Illinois State Board of Health, has been adopted by the State Board of Health of Missouri. This has been called the "Illinois Method." Reciprocity, of course, cannot apply in the case of the physician who was in practise when the operation of the law in his own State began, and who consequently never passed an examination to qualify him to practise. If he moves to Illinois, however, and wishes to continue in the exercise of his profession, the State Board makes it easier for him by reducing the percentage which must be obtained, by five for every five full years the applicant has been in practise.

Alabama.—In this State there is not only a State Examining Board, but also a county board, so that a candidate can, to some extent, choose his examiners. But as there are sixty-seven counties in the State, so there are sixty-seven standards of examination. This condition of affairs is not desirable, and at its last annual session the State Medical Association determined that the system should be abolished, and that as soon as possible only one board of medical examiners, the State Board, should exist in Alabama.

STATE BOARD EXAMINATION QUESTIONS.

MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.

October 9, 10, 11, 1906.

ANATOMY.

1. Describe the chief processes and general characteristics of the humerus.
2. What are the muscles of the forearm?
3. Describe the femoral artery.
4. Describe the collateral circulation after ligature of the common carotid artery.
5. Mention the principal convolutions of the brain. What are the ventricles of the brain?
6. What are the cranial nerves, and what do they supply?
7. Name the subdivisions of the alimentary tract and the accessory organs.
8. What are the lobes and fissures of the liver? Describe the gall-bladder.
9. What is the trigone vesical?
10. What are the muscles of the tympanum? What is the nerve supply to the tympanum?

PHYSIOLOGY.

1. Metabolism. Define and give classification.
2. When can a given amount of starch be said to have been completely digested?
3. Mention and give function of some one large system of veins beginning and ending in capillaries.
4. Give function of liver other than the secretion of bile—and mention varieties of blood found within the organ.
5. Blood. Trace its course through the heart and lungs, beginning at the right auricle. Describe the changes that take place.
6. Describe the function of the stomach.
7. Name all the valveless veins, and state why they have no valves.
8. Give function of kidneys.
9. State function of sympathetic nervous system.
10. Mention four elementary principles essential to health.

HISTOLOGY AND EMBRYOLOGY.

1. Name and describe the various forms of epithelial tissue.
2. Name the elementary tissues of special function.
3. Define and describe the lymphatic circulation.
4. Describe the formation and growth of the nails.
5. Give the structure of Peyer's patches.

CHEMISTRY AND TOXICOLOGY.

1. Define acid and base.
2. What is meant by "valence"? What is the valence of Ca., Na., and K.?
3. How is ammonia prepared?
4. Define the term anhydride.
5. Classify ferments found in the body. Name one member of each class.
6. Give the composition of the gastric juice. Give tests.
7. Give symptoms and treatment of poisoning from bichloride of mercury.
8. Describe opium poisoning. Distinguish between opium and alcoholic poisoning.
9. Describe cocaine poisoning.
10. Give symptoms of poisoning from the continuous use of acetanilide. Treatment.

BACTERIOLOGY.

1. Define bacteria; state methods for recognition, cultivation, and the conditions most favorable for growth, and the different ways of entering the body to produce disease.
2. Give details for the examination of sputum for the tubercle bacillus.
3. Describe method for determining the bacillus of tetanus, and state origin, form, properties, and growth.
4. What are ptomains, toxins, toxoids? What is an antitoxin—an antitoxic unit?
5. How would you make a bacteriological examination in suspected diphtheria? State dosage of diphtheritic antitoxin in pharyngeal and laryngeal cases, and in the different stages; also dosage for immunizing or prophylactic purposes.

SURGERY.

1. Local anesthesia. Describe agents and methods.
2. What is sepsis, giving symptoms and stages?
3. Describe the different amputations at the ankle joint.
4. Describe inguinal colostomy, giving indications for same.

5. Give differential diagnosis of dislocation of the femur.
6. Describe the complications of fracture, with treatment.
7. Describe osteomyelitis, giving etiology, differential diagnosis, sequelæ, treatment.
8. Give the surgical consideration of gastric ulcer.
9. Give diagnosis, cause, and surgical treatment of calculus.
10. Give diagnosis and surgical resources of intestinal obstruction.

GYNECOLOGY.

1. Describe the pathological effects caused by laceration of cervix, and all reflex disturbances therefrom.
2. What pathological conditions follow lacerated perineum; their immediate and remote manifestations, and, if operation be required, how soon should it be made, if not immediately following the injury?
3. What is vaginismus, its cause, and treatment?
4. What are the sources of streptococci poisoning in the puerperium, and in what per cent. of such cases does it occur? How should the local and constitutional manifestations of the disease be treated?
5. What is cystocele? Give symptoms and treatment.

OBSTETRICS.

1. External pelvimetry. Give procedure of taking external measurement, and enumerate the various normal diameters.
2. Tuberculosis. What influence does gestation have on the course of this disease?
3. Mention regulations for diet during normal pregnancy.
4. Give treatment of asphyxia of newly born.
5. Funicular presentation. Give etiology, diagnosis, and treatment.

PATHOLOGY.

1. Hyaline degeneration. Give its etiology and seats.
2. What is metabolism in diabetes?
3. Describe the lesions produced by excessive cold and heat.
4. Describe hypertrophy, and give its etiology and pathological anatomy.
5. Describe briefly the general structure of tumors, and discuss their classification.
6. Describe and give the pathology of congenital atelectasis.
7. Distinguish between fibrinous, catarrhal, purulent, and fibrous pneumonia.
8. Give pathology of chronic salpingitis.
9. Differentiate between caries and necrosis, giving etiology and pathological anatomy of the latter.
10. What is osteomalacia?

PRACTICE OF MEDICINE.

1. What are the remote effects of syphilis of the nervous system?
2. Mention some of the more common diseases of the heart; their diagnosis, prognosis, and treatment.
3. Describe pleurisy, both serous and purulent; diagnosis.
4. What is the prognosis in serous pleurisy?
5. What is the prognosis in purulent pleurisy?
6. What are the symptoms in gastric ulcer? Differentiate from duodenal ulcer.
7. Describe the characteristic physiognomy in typhoid fever, tetanus, and exophthalmic goiter.
8. Give the dietetic management of acute pneumonia, gastrointestinal indigestion, and chronic parenchymatous nephritis.
9. What is the clinical difference between diphtheria and streptococcic infection of the throat?
10. The cause and treatment of scurvy?

EYE, EAR, NOSE, AND THROAT.

1. What is trachoma; its cause; symptoms; course; prognosis; medical and operative treatment?
2. Describe the Argyll-Robertson pupil, and give its significance.
3. Describe the organs of the nerve supply of the function of hearing.
4. What is chronic nasal catarrh—its pathological anatomy, and treatment?
5. Describe the larynx and its cartilages—the laryngeal ligaments and the vocal cords.

MEDICAL JURISPRUDENCE.

1. What do you understand by the term Medical Jurisprudence?
2. A dead body is discovered in some sequestered spot, with or without marks of external violence. How would you proceed to make an examination of said body?
3. Differentiate between wounds inflicted before death, and those inflicted after death.
4. Define insanity from a medicolegal standpoint.
5. What constitutes malpractice?

HYGIENE AND PUBLIC HEALTH LAWS.

1. Define the term hygiene as related to the science of medicine, and state what you understand by health laws.
2. What diseases may develop from the use of impurities in water? Impurities in milk?
3. What deleterious gases accumulate in an imperfectly ventilated school room, and state amount of fresh air required per minute for each child; also state evil effects from the inhalation of air rendered impure by respiration.
4. Name most improved methods of disinfecting living rooms. State what precautions should be observed in typhoid fever, and with regard to the sputum of tubercular patients.
5. What diseases must be reported to the board of health? State fully the duties of the physician as required by our statutes.

MATERIA MEDICA AND THERAPEUTICS.

1. Explain what is meant by empirical use of remedies and their intelligent employment, and give examples.
2. Describe some of the so-called remedies much in vogue during the past fifty years which are now deemed worthless, if not harmful in certain cases.
3. Describe hypnotics, and the two classes into which they may be divided. Give examples.
4. What are anthelmintics? Vermifuges? Vermicides? What are the parasites against which they are directed?
5. What are the physical properties of amyl nitrite? Give its effects and therapeutics.

Nebraska State Board of Health.

May 29-31, 1906.

ANATOMY.

1. Briefly describe the animal cell and the reproductive cell.
2. Name contents of the mediastinum.
3. Describe the occipital bone, naming articulations.
4. Describe the pleural membranes, and name arteries and nerves.
5. Give origin and distribution of the 5th pair of cranial nerves.
6. Give origin and insertion of the flexor muscles of the thigh.
7. Give origin and distribution of the sciatic nerve.
8. Describe the orifices of the diaphragm, naming structures that pass through each.
9. Locate the arch of the aorta, and name its branches.
10. Describe the prostate gland.

PHYSIOLOGY.

1. Describe the red blood corpuscles as to (a) origin and fate; (b) form; (c) size; (d) number; (e) function.
2. What is understood by endocardiac pressure? State the causes of the pressure in the arteries, capillaries, and veins.
3. Give the accepted theory regarding the mechanism of the secretion of urine.
4. Give the successive steps in the digestion of a meal of roast beef and potatoes.
5. Describe the temporary and permanent teeth, and the usual age for the eruption of each.
6. Describe the normal sounds of the heart, and state how they are produced, and where they can be most distinctly heard.
7. Describe the bile and its uses. Give test for bile.
8. Name one property common to all blood leucocytes. Give some of their physiological uses.
9. Write briefly on internal secretions.
10. Discriminate between the corpus luteum of pregnancy and the corpus luteum of menstruation.

CHEMISTRY.

1. Define organic chemistry, atom, and element.
2. How modify cow's milk to approximate human milk?
3. Write an equation showing production of H. and laughing gas.
4. Give chemical tests for strychnine and arsenic.
5. Define fermentation and putrefaction.
6. Describe accurately Heller's test for albumen.
7. What reaction, normal or abnormal, may be produced by that test?

8. What average amount of solids in urine, and how estimated?
9. What are the common determinations in chemical examination of gastric juice?
10. What is the composition of proteids?

SURGERY.

1. Name the most common curvatures of the spine; give etiology, symptoms, treatment of lordosis.
2. Give etiology, symptoms, and treatment of empyema; give diagnosis of empyema, hemothorax, and bronchiectasis.
3. What is a ranula? Treatment.
4. Give differential diagnosis of the following conditions: Intussusception, floating kidney, stricture of pylorus, bubonocele, varicocele, and undescended testicle. Describe fully the technique of operation for varicocele.
6. How would you treat a lacerated and contused wound of the hand?
7. Etiology, symptoms, clinical history of carcinoma of breast. Describe in detail operation.
8. Give technique of amputation through middle third of the thigh.
9. What is the significance of pain in the abdominal region?
10. Describe in detail two of the most common varieties of clubfoot, and give surgical treatment of each.

OBSTETRICS AND GYNECOLOGY.

1. Describe the human embryo at the second, fifth, seventh, and ninth months, giving size and weight.
2. Describe the symptoms, and give the management of an incomplete abortion.
3. Describe a case of phlegmasia alba dolens, giving diagnosis, time of occurrence, cause, termination, and treatment.
4. Differentiate ovarian cyst, ascites, and pregnancy at beginning of fifth month.
5. Describe a case of puerperal fever, giving cause, time of invasion, symptoms, and course.
6. Name and describe fully the contents of the uterus at full term, before labor begins, detailing the presentation and position of the child most frequent, in an uncomplicated, healthy case.
7. Enumerate the symptoms which indicate the death of the child *in utero*, and state what course should be pursued in such a condition.
8. Describe in detail operation for repair of (a) lacerated cervix, (b) for complete laceration of perineum.
9. Give in detail the anatomy and physiology of the pelvic floor.
10. Name the different varieties of metritis; give causes, possible sequelæ, and treatment.

PATHOLOGY.

1. What is pathology?
2. Describe embolism and thrombosis.
3. Define and describe phagocytosis.
4. What is a neoplasm? Give some examples.
5. Describe sarcoma, fibroma, lipoma, myxoma, osteoma, and glioma.
6. Describe a primary and a secondary anemia, and give examples.
7. Describe pernicious anemia, chlorosis, leukemia.
8. Describe phlebitis, varieties, common causes, and course.
9. Describe and differentiate between gastritis, ulceration of the stomach, and cancer of the stomach.
10. Differentiate between arthritis deformans and acute polyarthritis.

PRACTICE.

1. Give symptoms of myxœdema. Give treatment.
2. Name the acute infectious exanthemata, giving period of incubation and specific bacterium of each.
3. Give diagnosis and treatment of acute eczema of the face in an infant.
4. Describe in detail the most common method used in the examination of stomachic conditions. Give diagnostic value of absence or presence of acids and juices, and significance of conditions found present.
5. Describe diagnostic significance of hematuria. Give etiological factors. How would you differentiate whether the kidneys or bladder were affected?
6. Give differential diagnosis of interstitial and parenchymatous nephritis. Give pathology of both diseases.
7. Give diagnosis, prognosis, and treatment of chronic pulmonary emphysema.
8. Give causes, diagnosis, and treatment of chorea.
9. Explain the diagnostic significance of the "knee jerk."
10. Give the abnormal heart sounds, and the point of greatest intensity of each.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending October 27, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	336	159
Diphtheria	238	25
Measles	51	—
Scarlet Fever	90	3
Smallpox	—	—
Varicella	42	—
Typhoid Fever	127	27
Whooping Cough	38	6
Cerebrospinal Meningitis	11	5
Malarial Fever	...	.....
Totals	933	225

The Cerebrospinal Fluid in Pernicious Malaria.—Nicola Pende has made a study of the cerebrospinal fluid in five cases of pernicious malarial fever of grave type, with reference to cytodiagnosis and physicochemical characteristics. The amount of fluid drawn was never more than twenty cubic centimeters. In normal cases there is a great deal of difference in the pressure of the fluid, which in some cases comes out drop by drop, while in others it flows continuously. In the five cases examined the cerebrospinal fluid was altered in its physicochemical properties as well as in its cytodiagnostic phenomena. The osmotic tension is diminished. There is hypotonia in cerebrospinal meningitis, and the same condition is found in the nervous conditions of grave cases of malarial infection. There is also in some cases lymphocytosis, which makes the diagnosis from meningitis extremely difficult. The percentage of chlorides is diminished in malaria. To understand these changes we must consider the serious alterations of the endothelium of the capillaries that has taken place and the obstruction of many of them by parasitic thromboses which interfere with the normal vascular circulation. There is a diminished molecular concentration of the fluid, lymphocytosis, and the presence of pigment and other poisons in the circulation.—*Il Policlinico.*

Treatment of Valvular Diseases of the Heart.—George Murray Waters declares that in fully compensated conditions no medicinal treatment is needed except keeping the bowels well regulated. The patient must lead a quiet, orderly life, free from mental excitement and bodily strain. Tobacco and stimulants must be used in severe moderation if at all; and the skin should be kept active by daily sponge and weekly tub baths of short duration. Moderate exercise, though never to the extent of fatigue or embarrassed breathing, is indicated, but even this should be supervised by the physician in charge. Especial care should be taken in the management of the aortic heart defect, and the patient repeatedly warned against excesses of all kinds and especially sexual indulgence. In the condition of lost compensation, absolute rest is of the first importance. The clogged venous system must be relieved by depletion. This is best accomplished by the use of cathartics such as calomel, blue mass, or compound jalap powder. Digitalis alone or combined with strychnia in moderate doses will strengthen the heart force, regulate the rhythm, and add tone to the organ generally. The writer adds that special symptoms, such as dyspnea, cardiac distress, gastric disturbances, cough, insomnia, and renal inactivity are relieved chiefly by means of the general rules set forth. Special treatment may be required in each according to the condition of the individual case.—*The Columbus Medical Journal.*

A PLEA FOR A MORE RATIONAL THERAPY IN TUBERCULOSIS.*

BY F. M. POTTENGER, A.M., M.D.,

MONROVIA, CALIFORNIA.

As long as tuberculosis was looked upon as hereditary, little or no headway could be made in its prevention. It was considered to be a matter of fate, and consequently surrounded by an air of hopelessness. The discovery of the specific cause not only paved the way for the overthrow of the heredity theory, but also made it possible for the disease to be discovered earlier than before, thus bringing it before the medical practitioner at a time when many cases are curable.

Pathologists had seen evidence of healed tuberculosis postmortem; but now the profession is able to find the bacilli in the sputum and then see the patient get well. The evidence of the curability of tuberculosis has been accumulating so rapidly that we know the disease which was considered to be one of the most hopeless a quarter of a century ago is now recognized, not only as the most curable of all chronic diseases, but the proof is overwhelming that, if diagnosed early and treated intelligently, it will afford a mortality even lower than pneumonia and typhoid fever. In spite of all this evidence, we not infrequently hear physicians say that they never saw a genuine case of consumption get well. Such statements reveal not only a limited experience with tuberculosis, "for genuine cases of consumption do get well," but they also show a lamentable lack of appreciation of the most valuable lessons connected with this disease, viz., that tuberculosis can be diagnosed early before breaking down occurs, and before the advent of that complex condition known as consumption, and that the earlier the diagnosis the more favorable the case for treatment. That most cases of far advanced consumption die is not evidence against the curability of tuberculosis, simply a rebuke to the carelessness of the patient in not seeking medical aid soon enough or to the medical attendant for not exercising sufficient skill to detect it when the disease presented.

To-day the curability of tuberculosis is established. No one conversant with facts will deny it. But the question which will bear discussion is, are we curing as many of the cases as we should? Are we curing as many as we can? Are we doing as much in the way of treatment of this disease as is possible, or are we falling into a dangerous rut? Are we worshiping at the shrine of fresh air, good food, and hygiene, and closing our eyes to many other important and helpful measures? Have we advanced only a degree beyond the fetiches of cod-liver oil and creosote to fall worshipers at the altar of fresh air? True, the advance is welcome. It is a wonderful improvement, but whoever would treat a disease so serious as tuberculosis should worship at no shrine except results. He should endeavor to use all remedies and measures which will aid in producing a cure.

As a basis for such a discussion as this, it is well to inquire into the causes which lead up to a cure in tuberculosis. What is it that makes it possible for the organism to overcome the tubercle bacillus and the results of its activity?

Osler is quoted as saying, "Make the patient fat and the local disease will take care of itself," thus making the cure a matter of nutrition. Great stress is laid upon nutrition by all phthisiotherapists, yet all who have had a wide experience know that it is not all. There are many exceptions to Osler's statement. Often we see patients who are thoroughly nourished, and who are progressing favorably toward recovery, begin, through no indiscretion of their own, to go down. The disease does not "take care of itself." Nature cures most of her cases of infectious disease, in spite of a low grade of nutrition. The cure of tuberculosis is more than nutrition. If it were not, we would not see men in robust health become tuberculous; yet every one of us has seen this occur. True, a well-nourished man does not stand in much danger, comparatively speaking, of becoming infected. The inoculation, if of a few germs only, will not produce the disease; however, if there be a great number of germs of a low virility, or fewer of a very virile strain, even well-nourished individuals will not be able to overcome the germs.

Where tuberculosis has made any considerable advance in the system, we have a tendency for it to spread. So many bacilli may invade new tissue at one time that no matter what the nutrition of the patient, the bacilli will gain the day. We, who follow these cases carefully, see this thing happen very often. So, if we can administer any remedies which will increase the natural resisting power of the body and keep the healthy parts bathed in serum rich in antibodies, we are doing more than we can by nutrition alone.

Modern studies in immunity show that bacterial diseases produce toxic elements, which stimulate the cells of the organism to the formation of defensive bodies, which thus tend to cure the disease. To this tuberculosis is no exception; however, for certain reasons, the discussion of which we cannot enter into here, the toxins in this disease do not seem to be set free in the proper manner to be effective, so the disease does not limit itself when it has become well started. If this failure on the part of nature to furnish the natural stimuli for the cells can be supplied artificially, or if the defensive bodies themselves can be supplied, then another aid to cure has been found.

That the use of certain culture products will supply this want has been thoroughly established. The original tuberculin of Koch, his later preparations, as well as numerous preparations made by other men, when used properly, will stimulate the cells of

*Read before the Arizona Medical Society at its meeting in Phoenix, Arizona, April 24 and 25, 1906.

the individual suffering from tuberculosis to the formation of defensive bodies, as is shown by the increase of the agglutinating and opsonic power of the blood. Further proof of their value is shown in certain cases of tuberculosis which fail to respond to ordinary open air, dietetic, and hygienic treatment, but improve at once when tuberculin is added to the treatment. There are also certain sera which seem to furnish the antibodies already formed which are of some value, the best known of which are the Fisch, Maragliano, and Marmorek.

Aside from the matter of nutrition and culture products, we can do much for those suffering from tuberculosis by alleviating certain symptoms, relieving certain complications that may be present, and putting the diseased organs in that condition which is most favorable for a cure. These, then, are the lines upon which we should base a rational therapy for tuberculosis. Not any one of them should be employed to the exclusion of the others, but all should be worked out into one harmonious whole. Of those remedies and measures which have been put forth as "cures" for tuberculosis in the past, nearly all have some merit, although the merit is not always where it is supposed to be. Cod-liver oil certainly increases nutrition when well borne, although there are more palatable ways of accomplishing this end. Creosote will often improve nutrition by its action upon the digestive system. When given in too large doses, however, even in suitable cases it does harm. It also has a beneficial effect upon the mucous membranes of the air passages, but to think that it will kill the bacilli by its antiseptic action is positively absurd. The pneumatic cabinet is based upon the idea of exercise for the lung; nitrogen gas, upon rest for the lung. The various culture products find their basis in the natural defenses of the organism. Perhaps none of these measures is wholly bad, but none of them should be put forth as a "cure;" they are aids to a cure. They, and many more remedies and measures, find a rational basis for employment in the treatment of certain cases of tuberculosis, but they are not to be used in a routine manner. The treatment of tuberculosis is a matter of careful individualization.

Recognizing the importance of nutrition, it should be one of our chief aims to maintain this at the highest point. Everything which interferes with it must be eliminated. The hygienic-dietetic-open-air treatment, which is deservedly so popular throughout the world to-day, has for its basis the betterment of nutrition. One of the most noticeable, and perhaps the most important effect of the open-air treatment of tuberculous patients, is its effect upon digestion and assimilation. Coincident with the beginning of this treatment we note a marked improvement in the appetite. When digestion has been previously slow, and attended with more or less unpleasant symptoms, we not infrequently observe a disappearance of all embarrassment. Assimilation improves, and the patient takes on flesh. The effect of the open air is to enable the patient to digest and assimilate more food and to furnish the appetite which demands it.

The best effect of open air can be obtained only by using it discreetly. While in itself harmless, doubtless more lives have been wrecked while trying to follow this mode of treatment than by any other measure. Open air is not a cure for tuberculosis; it is only a measure for the production of a certain end. If used properly, it is one of the greatest aids to nutrition that can be employed; if used improperly, it will defeat its own purpose.

An individual suffering from tuberculosis should not be told that open air will cure him, but that proper living in the open air will be one of his greatest aids. Many an individual has eaten good food and remained in the open air all the time, and yet killed himself. The oft-repeated advice of well-meaning eastern physicians to their patients to "go West, live in the open air or rough it, and keep away from physicians," is responsible for the deaths of hundreds of patients annually. Not open air, but the proper use of open air, is one of the chief aids in the cure of tuberculosis.

Open air should be supplemented by proper food and carefully regulated rest and exercise to make it most effective. While we recognize that rest is a wonderful aid to nutrition, and that overexertion decreases the resisting power of the patient, yet there comes a time in the treatment of nearly all cases of tuberculosis when exercise short of tiring will increase nutrition and hasten recovery. The physician must be the judge when this time comes.

Beside prescribing open air, a carefully selected diet, and the proper amount of rest and exercise, the physician must control and regulate the entire life of the tuberculous patient. He must guide him even to the minutest detail of his life. Nothing of importance should be left to the patient's judgment until he has proven himself competent.

Another measure of great value in improving nutrition is hydrotherapy. The careful and intelligent application of water offers us one of our most valuable and most flexible aids to nutrition, and should never be omitted.

Climatic conditions affect the state of nutrition very decidedly. While sunshine is not indispensable to the treatment, as is shown by the results obtained in many places where there is a large percentage of cloudy days, yet those of us who are fortunate enough to be able to give our patients the benefit of almost constant sunshine realize its value. Its cheering and tonic effect is a very potent factor in aiding nutrition. A climate which not only affords an opportunity, but which invites the patient to be out of doors a great portion of the time, and which also affords a large amount of sunshine, is a great aid in the treatment of tuberculosis.

Modern research points to the possibility of the laboratory giving us cures for all bacterial diseases. Vaccination of bacterial toxins is assuming an important and rational place in treatment. It is now about fifteen years since the first efforts at specific treatment in tuberculosis began. This first trial of tuberculin marks one of the saddest pages in the history of the treatment of this or any other disease. Never were hopes raised higher, and never were they dashed lower. The misuse of tuberculin in the early nineties not only resulted in the death of many patients, but it so embittered the medical profession against it that it will still take time before the remedy can be assigned its proper place. During all these years those suffering from this disease have been denied the help which could have been rendered by this immunizing treatment. The persistence of a few men, however, such as Spengler, Petreschky, Turban, Goetch, Trudeau, and von Ruck, who were convinced of the value of tuberculin, has finally made the profession reconsider and give a more favorable opinion.

Laboratory experiment, as well as clinical evidence, shows that tuberculin will aid in the cure of tuberculosis. Its effect on local lesions, such as can be seen by the eye, in the larynx, for example, proves its value beyond question. The increase in the agglutinating and the opsonic power of the blood

of those patients who are treated by it, shows that its action is that of a specific immunizer.

Tuberculin stimulates the cells of the body so that they throw out more specific antibodies into the bloodstream, and should be employed in the treatment of this disease. So we can do more than nourish our patient; we can artificially increase his resisting power. We can make him more able to destroy the tubercle bacilli and the toxins which they form.

Since the important researches of Wright and Douglas upon the opsonic power of the blood have shown us that Buchner and Nuttall were right in ascribing an antibacterial action to the serum of the blood, we can see the wisdom of keeping areas which are infected with tubercle bacilli well bathed in serum. The action of the Finsen light is to cause an irritation, with an increased flow of blood to the part. Poultices to certain lupus patches have hastened their cure. Bier's method of treating tuberculous joints, as well as acute inflammations, by passive congestion, can be explained in this same way. In this way we can also explain the action of violet light upon pulmonary tuberculosis. By causing an active hyperemia it is aiding in bathing the parts with serum. Thus, all these measures which tend to divert more blood to the part involved are of value, and should be used in connection with tuberculin, for by so doing we are bathing the diseased areas with a blood which is rich in antibodies.

Another measure which is of value is the giving of raw meat or muscle juice. Experiments of Richet and Hericourt, also of Philip and Galbraith, show definitely that the employment of raw meat and raw meat juice causes a much greater retention of nitrogen than when the meat has been cooked. It is also the belief of these writers that there is something specific against the muscle waste, in the ingestion of the raw muscle.

In order to be most successful in the general therapy of tuberculosis, all distressing symptoms and complications should be carefully managed. It is rarely necessary to give medicines for cough, night sweats, shortness of breath, loss of appetite, indigestion, or fever of the early or moderately early cases. The careful management of the patient, putting him to rest in the open air, together with the proper hydrotherapeutic measures, will usually relieve all these symptoms very quickly. Organic diseases of the stomach should receive most careful attention, for a good stomach is indispensable. The bowels should also be kept active. In more advanced cases, sometimes these distressing symptoms will have to be relieved by appropriate drugs.

Among the most distressing complications are dry pleurisy, which can be best relieved by strapping, and pleurisy with effusion, which should be removed if it causes embarrassment of the heart or respiration; tuberculous laryngitis, which will yield most readily to tuberculin, local cleanliness, rest, and wet packs; and tuberculosis of the bowel, which will require careful regulation of the diet and such harmless astringents as bismuth in large quantities, or lead and opium in intractable cases. The tuberculous patient is also subject to all other "ills that flesh is heir to," and when present they must be treated carefully.

Mixed infection is a very serious complication. Tuberculosis does not long remain a simple process. Germs, other than the tubercle bacilli, soon gain entrance to the diseased areas, thus complicating the condition. Just what part mixed infection plays in the pathology of tuberculosis is as yet uncertain, but the advent of other germs is generally looked upon as being a serious complication. Mixed infection unquestionably hastens destruction of tissue in the local areas and causes the liberation of toxins which are responsible for many grave constitutional disturbances.

Mixed infection is doubtless present early in the infection, long before we are wont to recognize it by the symptoms which are usually ascribed to it, and it is undoubtedly the part of wisdom always to bear this in mind in treatment. When the symptoms have once become marked the patient should be put to bed in the open air. The temperature should be relieved by sponging, the patient should be encouraged to eat plenty of good food, taking solid food at that time of the day when the temperature is low, and relying on milk, eggs, and muscle juice mostly at other times. All distressing symptoms should be relieved, and the patient kept in as cheerful a condition as possible. Every effort should be made to keep up the patient's nutrition. It is not at all uncommon to find patients who are thus carefully treated run a course of fever for weeks, and yet gain in weight.

The most dangerous germ found in these cases of mixed infection, and the one which is nearly always present, is the streptococcus. If we can overcome it, the other germs will usually cause little trouble. A very efficient remedy against these germs is streptolytic serum. The difficulties in its use are that it is expensive, it requires to be used in large quantities for a long period, and its action is not always certain. But it is undoubtedly a remedy worthy of use and a great aid in this usually-considered helpless condition.

Aside from mixed infection, fibroid changes, necrosis, and in some instances calcification, occur in the diseased areas. From the blocking up of the blood-vessels in the lung there is a damming back of the blood, with more or less passive congestion of the internal viscera; the heart has an extra burden thrust upon it, and its muscle, weakened by the strain, often becomes damaged. Cavities form in the lung; contraction occurs. That part of the lung which is not affected hypertrophies, and becomes emphysematous, thus adding more burden to the heart; the general system is poisoned by the toxin; wasting occurs, and all organs suffer more or less. This gives us the picture of consumption. This is what we are trying to relieve when we attempt the treatment of advanced cases of tuberculosis. Tuberculosis is a disease, consumption a condition resulting from the disease. When we have done all we can for such cases we have done little enough. Fresh air will do much for them, but it comes far from being the only thing that can be done. Every such case must be made a study of itself, and then, by careful attention to details of treatment, much can be done, even for many of these advanced cases.

Until the medical profession becomes more alert at early diagnosis, we cannot hope to treat our cases in that early stage when at least three-fourths of them should be cured, but must direct our efforts toward the relief of the cases as we find them. There is one thing gratifying, however, in the treatment of advanced cases of tuberculosis, and that is that much more can be done for them than is usually supposed. Some of those who are even far advanced can be cured, many of them can secure an arrest of their disease, and most of them can be improved.

In order to obtain such results, however, we should worship no idols, neither cod-liver oil, creosote, climate, open air, or tuberculin. We should grasp the full meaning of the pathological process

with which we are struggling, and then endeavor to apply our therapeutic measures accordingly, remembering that it is far better to attack an enemy at every vulnerable point than at one alone. While I am a firm believer in the open-air, dietetic, and hygienic treatment of tuberculosis, and recognize it to be one of the greatest advances of modern therapy, yet I should dislike very much to see our therapeutic efforts stop here. My plea is for a broader view and a more rational therapy, not only one based on nutrition, but one which considers the disease in all its varied aspects.

NEURASTHENIA.

By HUBERT RICHARDSON, M.D.,

BALTIMORE, MD.

LECTURER ON PHYSIOLOGICAL CHEMISTRY AND ON NEUROLOGY AND PSYCHIATRY, UNIVERSITY OF MARYLAND; PATHOLOGIST TO THE MARYLAND HOME FOR FEEBLE-MINDED CHILDREN.

NEURASTHENIA as a definite form of nervous disease was first described by Beard of New York, in the *Boston Medical and Surgical Journal*, 1869, followed by a paper read before the New York Academy of Medicine in 1878; he further elaborated the subject in a work entitled "Nervous Exhaustion," which reached a second edition in 1890; later he published "Sexual Neurasthenia," where he attempted to place a number of different nervous troubles under the same heading, including hypochondria, hysteria and sexual perversion.

Neurasthenia is a disease most often found in hospitals in its uncomplicated form, but often accompanied by other morbid conditions which mask its symptoms, rendering diagnosis difficult. During the writer's connection with Mount Hope Retreat, and also in private practice, he has had the opportunity of observing a considerable number of cases, and he attempts in this paper to give a symptomatic picture of the disease for the benefit of the general practitioner, who is usually the first consulted by the patient. The treatment by the general practitioner is usually entirely symptomatic, consisting of bromides in increasing doses, with the addition of hypnotics, the various coal-tar products, and headache powders, with little or no effort to treat the underlying condition; the patient becomes worse or fails to improve, finally consulting a specialist or entering an institution.

These patients usually come from the city, though, perhaps, if the statistics of the relation of the cases to the population from which they are drawn were obtainable it would be found that there was little or no difference; many of the cases I have met with were in farmers and country business men. In practically all cases, however, the disease affected those who worked with their brains, and it is very rare indeed to observe it in the laboring classes, suggesting that want of physical exercise is a factor in its etiology. The disease appears in adult life, rarely in youth, and probably never in children. In my experience there has been a greater proportion of cases among women than men, but this probably is incidental to the nature of the practice.

There are certain principal symptoms, or, better, stigmata, of the disease, some psychical, some physical, a knowledge of which is necessary for a diagnosis.

Headache, which exists in about 90 per cent. of all cases, has the peculiarity that it is at its worst in the morning, gradually decreasing as the day advances, and disappearing at night, only to recommence the following morning; during the day there are usually slight ameliorations of the pain, especially at meal time, increasing again as digestion advances. The pain is a heavy, dull, numb feeling in the head, with perhaps occasional lancinating pains or paroxysms of intense agony. The decrease of the pain at meal time is of short duration, for when digestion is at its height the pain is increased, accompanied by flushings of the face, giving the appearance of plethora with a feeling of intense malaise and depression. Toward evening the headache declines; usually there is a severe attack after the evening meal, after which it may disappear entirely during the night, so long as the patient keeps the recumbent position; but, on standing up, it returns, and in the morning commences again.

The headache is either bitemporal, surrounding the head like a vice, or more often it is in the occipital region, the whole of the back of the head to the nape of the neck having the sensation of a grinding or crackling, which may be so intense that the patient imagines he can feel the sensation with his hand. At other times the whole head is affected; the skull may feel too small for its contents; at others there is a sensation as if the brain were boiling; the forehead is flushed, giving a sensation of heat to the hand, but the body temperature is normal, or nearly so.

Though the headache ceases or lessens at night, the patient suffers from insomnia which may be of either of two kinds. In one he falls into profound, heavy sleep immediately on lying down, only to awake in two or three hours to spend the rest of the night in tossing about till morning, a victim of a thousand miserable sensations, turning from side to side from a feeling of discomfort, especially in the lower limbs, of shooting pains, prickling, stinging, and general teasing sensations, followed by a feeling of numbness which is almost unbearable. He may doze for a short while at last, but he is compelled to rise, tired and unrefreshed, the headache returning as soon as he puts his feet to the floor. Should he doze for a few minutes the arm under the body becomes numb, paralyzed, dead; in a minute or two the sensation disappears, but the condition is renewed, and he takes all sorts of uncomfortable positions to avoid its repetition, effectually dispelling any tendency to sleep; at other times the lower limb appears to have a sort of shock or sudden contraction, which is very disquieting. In other cases complaint is made of a feeling of emptiness in the epigastrium, with gurglings in the intestines, more marked in the morning. Urination is often frequent during the night, suggesting Bright's disease or diabetes, but there is no sugar in the urine, and only traces of nucleoalbumin are present. Under the above conditions sleep is evidently impossible, though toward morning the patient may pass into a doze or sleep for a short time, but is soon compelled to rise as tired and miserable as when he went to bed.

The other form of insomnia differs from the above in that immediately after the evening meal the patient has apparently an almost uncontrollable desire to sleep, but once in bed he is wide awake, the entire night being spent in short snatches of semi-unconsciousness, in which he hears the clock strike every hour; the least noise seems to his tired senses magnified one hundredfold;

the pressure of the bedclothes irritates him, and he passes the whole night without any sleep which is of benefit to him. It is evident that the patient can have no desire for his daily avocations, the headache commencing as soon as he gets up, and the day of misery and ennui repeating itself. Another peculiarity is that as the patient is dropping off to sleep he awakes with a sudden start, and his rest is disturbed by "night terrors," delusions, feelings of dread and disturbing dreams.

Another symptom is a vertigo presenting special characteristics. It is not like the vertigo of Ménière's disease, in which there is a true loss of equilibrium and the patient falls—it is a sensation of emptiness of the head, accompanied by a weakness of the limbs; a cloud comes before the eyes, all appears gray with black moving spots, objects near and far are confused and seem to be on the same plane. These phenomena resemble accommodative asthenopia, which often coexists with vertigo; examination of the eye reveals little or nothing; the pupils may be dilated, usually equal in size, reacting a little slowly to light, and the retina is normal. These attacks of vertigo are most apt to occur on the patient rising from the recumbent, or sitting, to the erect position, or when any emotion is evoked, however slight. A form of agoraphobia may exist, the patient being afraid to walk along the street or to pass through a door, for fear the walls will fall upon him, or an open space may produce intense sensations of fear. The vertigo shows itself most often in the morning, and, like other symptoms, it is less frequent during and immediately after meals, generally disappearing in the evening, and never occurring in bed.

In some cases there are pains in the spinal column, either in the cervical or at the junction of the lumbar and sacral vertebræ. The pains radiate in the former case toward the shoulders and arms, causing a sensation of weight and oppression; in the latter case the same feelings are experienced in the lower limbs. The patient locates the pain in the column exactly, but examination reveals nothing, except perhaps a slight hyperesthesia; there may be a sensation of feebleness and numbness suggesting paraplegia, but the sphincters are normal; the reflexes may be normal and equal on both sides, though exaggeration is not infrequent. The headaches and vertigo suggest organic brain trouble, the pains and symptoms from the cord suggest spinal trouble, and mental depression, insanity; and careful analysis of the clinical symptoms is necessary to form a correct diagnosis.

The stomach and intestines are also more or less affected in neurasthenia, suggesting autointoxication; there is retarded and difficult digestion; on rising the tongue is coated and the mouth sticky; the appetite is poor; during eating and immediately after the painful sensations are milder, or they may disappear altogether, the general condition improving. A light breakfast is usually well digested, but it is necessary that another light meal be taken in an hour or two, or the patient will suffer. The condition of the stomach is one of continuous secretion of hydrochloric acid with a want of motility; it is therefore necessary that the neurasthenic be fed frequently at short intervals, and on no account should he eat a large meal. Although the hydrochloric acid is being continuously secreted in small quantities, the glands are in a state of fatigue, and are therefore unable to respond to the demand for the excess of hydrochloric acid necessary for a large meal. After a test meal the analysis gives various results; usually the amount of free and loosely-combined hydrochloric acid is normal, or slightly reduced, though at times there is a marked hyperchlorhydria. The test meal is never a very satisfactory method of diagnosis in a nervous patient. In the first place, the Salzer meal is not very appetizing, and is more than the patient cares to eat, consequently the "psychic juice" is not secreted in full amount; the Ewald breakfast is not appetizing, especially with American bread; in Germany the "Brödchen" is much more pleasant to the palate, which may have something to do with the larger amount of free hydrochloric normally found in examinations made in that country. To give a nervous patient a test-meal at 8 A.M., another at noon, and to draw his stomach at 1 P.M., during which time he is on a mental rack as to the terrible ordeal he is about to go through with the tube, is not calculated to produce normal digestion and give accurate results. Judging from the urinary analyses in these cases, one would consider that there was a marked hyperchlorhydria, and I believe that there are cases in which not only is the secretion continuous to a greater or less degree, but, on taking a full meal, there is a hypersecretion of hydrochloric acid which prevents proper peptic, and also retards pancreatic digestion. In many cases the digestive symptoms are secondary to the nervous trouble, though careful attention to the diet and digestive organs mitigates the suffering, especially the insomnia. It is evident that no disease can be treated successfully unless the nutrition is normal; the absorption of partially-digested proteids or imperfectly-converted sugars cannot but be detrimental to the general condition. Tympanites and acid eructations follow a heavy meal consequent on the general atony of both the stomach and the intestines, producing a certain amount of autointoxication, but the pathological condition of the nervous system is often primary, the digestive symptoms disappearing as the patient improves. The intestinal trouble consists usually in obstinate constipation, with occasional attacks of diarrhea, in which, on microscopic examination, there will be found blocks of mucus, evidence of membranous enteritis, a very common accompaniment of neurasthenia. In women there is often a mucomembranous dysmenorrhea. The general condition of the patient suffers, and flesh is lost rapidly, though in some cases the "embonpoint" is preserved.

The urine is clear, limpid, and large in quantity, suggesting hysteria, though at times it may be less abundant and dark in color. The urea nitrogen is low, the ammonia and uric acid normal, but the residual nitrogen is markedly excessive, and there is usually a marked phosphaturia; the proportion of chlorides to nitrogen is below normal, while the carbon-nitrogen factor is normal or low. Indol and ethereal sulphates may be high or normal, depending on the condition of the bowels, but the neutral sulphur is invariably high.

The heart suffers with the other organs; the maximum pressure is low in proportion to the mean, and extremely variable. Under normal conditions the taking of food raises the mean pressure, but in neurasthenia so marked is the arteriolar contraction of the abdominal vessels, that an intense flushing of the face takes place, with a

feeling of congestion of the brain, and a beating of the cephalic arteries. At other times, owing to the relaxation of the abdominal vessels, there is an accumulation of blood in the abdomen, causing a general sensation of cold; the hands and feet, especially, being cold. To a certain extent the vertigo is due to the same cause. On taking the erect position from the recumbent there is under normal conditions a rise of arterial mean pressure of about 10 mm. Hg., and a slight increase of the pulse rate; in the neurasthenic, on the contrary, there is a fall of mean blood pressure, on taking the erect position, of from 20 to 30 mm. Hg., and a very marked compensatory increase of the heart rate. This is, however, insufficient to overcome the want of arteriolar contraction, and an anemia of the brain is the consequence, producing a vertigo for a few minutes until the arteriolar contraction takes place, when the vertigo passes off; in other words, the compensatory vasoconstrictor mechanism necessary for the erect position is deficient, reacting slowly to the stimulation of standing up.

The physiology of the blood pressure has been but recently investigated, since Leonard Hill and Bernard introduced their sphygmometer, it being the only one which will record both the maximum and mean pressures; the Riva-Rocci instrument usually used in this country is of little use clinically, as it records only the maximum pressure, and, owing to its depending upon the sense of touch of the operator, the results are usually too low. Oliver and Hill have shown that any mental work or emotion raises the mean blood pressure, and it follows that continuous mental strain upon the vasomotor nerves will result in their enfeeblement; and, further, Sir William Broadbent has shown that continued mental strain produces a dilatation of the heart, the result of the continuous increased back pressure upon the ventricle. The effect of mental strain in the causation of neurasthenia will be referred to later, but enough has been said to show that primarily the neurasthenic condition is the result of a decreased sensibility or accommodative power of the vasomotor system.

Angina of a special type is common in neurasthenia; there is a little precordial anxiety, but no painful radiations to the left arm; the thorax seems as though it were held in a vice, the pulse, instead of being, as in true angina, small, thready and intermittent, is full and regular; the heart beats are strong, even violent; the sounds distinct. Sometimes there is hyperesthesia in the precordial region resembling somewhat the condition found in hysteria; though the attacks of this angina are severe, there is no danger of collapse. There is also a shortness of breath, oxygen hunger, the patient sighing frequently.

The functions of the genital organs are depressed, loss of power and desire are frequent causes of complaint. Coitus may be possible, but is followed by a feeling of intense lassitude, with increase of pain in the lumbosacral region. More rarely, the patient is troubled with nocturnal erections which coitus does not relieve, sometimes accompanied by emissions, increasing the weakness and mental depression. At other times coitus is incomplete, ejaculation following almost immediately an erection. These symptoms suggest disease of the cord. In other cases, each defecation is followed by an emission of a thin fluid containing spermatozoa; in this condition the prostate and vesicles should be examined for abscess and the discharge stained for gonococci. The writer treated a case which appeared to be a typical one of neurasthenia without headache, in which the patient recovered completely on the treatment of the prostate for a gonorrheal abscess; the spermatorrhea is due to atony of the seminal vesicles, and can be cured by cold douches in the rectum. Cases with the above symptoms have been classed as sexual neurasthenia, melancholia being a marked psychic symptom.

Another symptom, which, however, is rarely present, is a certain amount of tremor, usually slight, vibratory, affecting at the same time both the upper and lower extremities; the tongue is very rarely affected, but there may be a tremor of the lips, causing difficulties of speech which suggest paresis.

The mental condition presents a general depression of the faculties without perversion; usually the mental activity is increased, sometimes decreased; intellectual work becomes difficult, and, above all, the inability of the patient to make a decision on any matter, however trivial; the memory, though slow, is intact, and the judgment is normal. With an effort the patient is usually able to recover his mental aptitude completely, differing in this form from the true melancholic, in whom there are mental perversions, and from the paretic, who has more or less lost control of his ideas. The neurasthenic will describe his mental condition exactly, and the psychic depression from which he suffers without any impossibilities, exaggerations, or delusions, except that he has an exaggerated view of the severity of his case, with the idea that he is going insane, and that he will never recover. Restlessness is often a marked feature, the patient being unable to remain in one position, or to sit still for more than a minute or two at a time. Irritability in some cases is very marked, the patient breaking out into uncontrollable fits of temper on slight provocation, perhaps swearing and breaking the furniture, the symptoms resembling those of acute mania. Timidity may be a very marked symptom.

Constitutional neurasthenia is another form of the disease, according to Charcot and other writers, but the symptoms are the same, the subjects being those who are either congenitally, or from some acquired condition, less able to bear the nervous and mental strain of the struggle for existence, and who, therefore, more easily succumb to the strain of life. I do not believe that the pressure of civilization is greater now than in former years; if more work is accomplished, more responsibilities carried by the individual, than formerly, it must be remembered that the advantages of modern methods and appliances render such efforts more easy; and, besides, if the working strain is greater the opportunities for diversion and recreation are also greater than formerly. There is, perhaps, one condition in modern life which tends to produce nervous and physical breakdown, and that is that to-day the large majority of business men take but little exercise.

Our forefathers either had to walk, to ride horseback, or drive; in the latter case the time consumed on a journey was longer than in these days of express trains, and was to a great extent a rest from business cares, combined with a

change of scene and environment, which could not but be beneficial to the overworked man. We, however, see men to-day who have led active business lives for half a century or more, hale and hearty at eighty years of age, and again we see men whose responsibilities have been light, and whose anxieties have been few, succumb to nurasthenia.

In the so-called constitutional neurasthenia the clinical history reveals but little of the etiology of the case; as an example, a young man of thirty comes to the office with many of the symptoms detailed above; in his history is neither heredity, alcoholism, nor syphilis—those ever-ready refuges for the perplexed diagnostician; he may never have had any severe illness, and possibly the ordinary diseases of childhood have been so mild as to have almost escaped his recollection; he is possessed of a private income which renders him free from the anxieties of working for a living, and is, perhaps, working in some office more to employ his time than for pecuniary gain.

There is one point, however, in many of these cases which show the cause of the neurasthenic condition, viz., that puberty was delayed, that the patient ceased to grow at the age of about sixteen or seventeen; that he was backward mentally, not perhaps as calculated from the standard of the school, but rather in his psychic development, associating with boys younger than himself, and finding amusement in boyish or childish games. At about eighteen or nineteen the average boy becomes a man; he puts away childish and boyish things; but in this case he has remained a boy till perhaps twenty, or even longer. In women, in whom this form of neurasthenia is more common than in men, menstruation may not have commenced till eighteen or nineteen years of age, and always been more or less scanty and irregular. The genitalia of the male are often small and poorly developed, and there has never been much sexual desire. Such cases are not true neurasthenia; they may belong to the class of cases known to the French as "type Loraine," or they may be cases of infantilism, in which the thyroid has failed to develop fully, or has atrophied early; or they may be cases of anangioplasia. The mean blood pressure is high; the arteries feel hard and small, suggesting arteriosclerosis; the heart beat is rapid and forcible. These cases do not belong to neurasthenia, properly speaking, their etiology being very different, and consequently their treatment also. The prognosis, as regards perfect recovery, is, however, not good; the symptoms may be ameliorated, but the patient will probably spend the rest of his life under the care of a physician, dying at a comparatively early age from some intercurrent disease, owing to the reduced resistive power of the system.

True neurasthenia is found among those men who lead strenuous lives, having great responsibilities and anxieties, without taking a sufficient amount of recreation and physical exercise, combined with irregular and bolted meals. The importance of the digestive apparatus cannot be overestimated; its complications render it liable to get out of order; consider that the saliva, the pepsin, hydrochloric acid, enterokinase, pancreatic juice, with its three ferments, the bile, the succus entericus, and other ferments, which are as yet imperfectly understood, have all to secrete sufficiently, and in proportion, in order to convert the food into the condition in which it is most easily absorbed and assimilated, and that, if any links in the chain are omitted, the nutrition will suffer, not only from decreased assimilation, but also from the absorption of imperfectly digested food products which must act as poisons to the system.

The etiology of neurasthenia can be classed under four heads: (1) Mental strain; (2) disturbances of digestion, malnutrition, and autointoxication; (3) toxemia from infectious diseases; (4) traumatism, and shock.

It is a matter of general knowledge that emotions affect the digestion, anxiety and grief cause loss of appetite, coated tongue, constipation, etc., producing malnutrition and autointoxication, which, in their turn, act upon the already overstrained nervous system. In many cases of neurasthenia the digestive disturbances antedate the nervous symptoms; in others, the nervous symptoms are the first to appear, the one reacting upon the other in a vicious cycle.

Toxemia from grip, scarlet fever, diphtheria, and other diseases sometimes leaves the patients a nervous wreck. Traumatism and shock are a cause of the same condition as seen in those nervous troubles dating from railway accidents, etc.

It is apparently the vasomotor nervous system which is principally affected. All emotions act upon this system of nerves. Leonard Hill has shown how mental work raises the mean blood pressure 30 to 40 mm. Hg.; if the nervous mechanism is continually under a severe strain for months or years, it is evident that it will become fatigued, and refuse to act normally to stimuli. I have observed that there is a reversed postural blood pressure in neurasthenics; under normal conditions, on taking the erect position from the recumbent, the mean blood pressure rises from 10 to 30 mm. Hg., while in neurasthenics, under the same conditions, there is a marked fall, sometimes as much as 40 mm. Hg., with a great increase in the pulse rate, showing that the vasomotor system fails to respond to normal stimuli. In neurasthenia the blood pressure is variable and erratic, falling suddenly when it would normally rise, producing vertigo; at other times rising excessively, causing flushing of the head and neck, while the hands and feet may be cold. The vasomotor system regulates the blood supply to the various organs, and it seems probable that many of the nervous symptoms classified as separate diseases are due to a defect of the vasomotor nerves controlling the blood supply to some particular portion of the nervous system, the variations in the symptoms depending upon the part affected.

There is yet another etiological factor which is of great importance from a therapeutic standpoint, viz., a gouty constitution. In these cases the urine is intensely acid, and the carbon nitrogen factor very low. The most marked symptom is irritability of temper, sometimes so great as to resemble an attack of acute mania.

There is no specific treatment in neurasthenia. Removal of the cause of worry, if possible, increased physical exercise, anything to interest the patient in some form of recreation, attention to the digestion, to the removal of the toxins from the system, and to the building up of the whole system in every possible way. Drugs, such as the bromides, the coal-tar derivatives, etc., should be used as little as possible on account of their

effect upon the assimilation, the circulation, and the blood; the coal-tar preparations are particularly contraindicated on account of their destructive action on the red corpuscles. Bromides depress the heart and the vasomotor system, and should be used with caution. The difficulties of the physician are much increased by the intractability of the patient; he will refuse to leave his business, or perhaps he is unable to do so; he will not take his treatment regularly, will absent himself from the office for a week or two at a time, returning perhaps to scold the physician because he is not better, or perhaps he will seek a new doctor every month; it is no uncommon occurrence to have a patient produce a pocketful of prescriptions from different physicians, upon all of which he will dilate with a curious mixture of astuteness and perverted knowledge, which would be amusing if it were not tedious. The first duty of the physician is to gain the patient's confidence, and, by firmness and sympathy, hold him to his treatment, a task often of great difficulty, requiring great tact and patience.

ELECTRICITY IN THE TREATMENT OF DISEASE.*

By JOHN V. SHOEMAKER, M.D., LL.D.,
PHILADELPHIA.

In opening this discussion upon the therapeutic applications of electricity, it is very evident, at the outset, that in the short time permitted by the program I cannot make any adequate presentation of the subject, and I know that a systematic review of all the medical uses will not be expected of me. Current medical literature and the textbooks are crowded with the reports of an immense number of diseases and morbid conditions in which electricity, in one form or another, has been recognized as serviceable in therapeutics. Perhaps the best use I can make of the time at my command this afternoon will be to devote it to the consideration of a few applications that I have found especially serviceable in my own experience. In concluding, I will make a comment based upon personal observation with regard to the proper field of usefulness of this potent force. In order to obtain the best results in practice it is important that we shall bear in mind the limitations of electricity in clinical medicine, because if these are disregarded we may expect to meet with certain disappointment. Extravagant claims made by too enthusiastic advocates are not only unjust to this valuable therapeutic resource, but they are also unjust to the patients who are led to expect impossibilities.

I think it will lead to a clearer view of electricity from the medical standpoint if we lay aside for the moment any preconception we have in our minds with regard to its being a mysterious, life-giving force, capable of working miracles upon the human body, and as being at all times constructive, energizing, and beneficent in its effects in pathological conditions. This I know is the popular idea, which has been largely founded upon the seductive and boastful advertisements of charlatans, who have found this a fruitful field in which to work on the credulity of the ignorant public. "There is no sacred disease," said Hippocrates, "or all diseases are equally sacred." So we may say with regard to remedies, there is no mysterious remedy, or all remedies are equally mysterious.

*Read before the Pennsylvania State Medical Society at Bedford Springs, Pa., September 11, 1906.

Mercury, arsenic, and other potent drugs may, according to circumstances, act as caustic agents and destroy tissues, or they may act as tonics and favor physiological changes. In the same way electricity may be used in medicine to destroy tissue, or, on the other hand, to favorably influence metabolism, depending upon the form in which it is used and the skill with which it is applied.

Let us now briefly consider the forms in which electricity is utilized in medical practice. We observe, in the first place, that it is used both indirectly and directly. Among the indirect applications of electricity are those in which it is employed as a source of heat, light, magnetism, and x-rays. As illustrations of the former I may mention the galvanocautery, the electric light, and the Roentgen apparatus; also the electro magnet. Illustrations of the direct application are the galvanic, the static, and the induced currents, obtained from the ordinary medical coil or from the large commercial dynamo. The latter, however, is much more powerful than is required for medical purposes, but it may be reduced by transformers and controllers, or "stepped down" so that it can be used therapeutically, as well as for heating and lighting the doctor's office.

The first point that I wish to make is that electricity is always the same in itself, but, like the other agents I have named, it may be given in different dosage and in different ways, so that entirely different therapeutic results may be obtained. Success in therapeutics, whether in the use of electricity or any other remedial agent, depends, as we know, very largely upon the personal skill and good judgment of the physician who makes use of it. Incidentally, I may observe that this method of regarding the subject will help to explain why certain conditions, such as neuralgia, may be treated successfully either by galvanism, static electricity, or by the Roentgen ray; these apparently different forms of electricity being skilfully employed to produce apparently the same local effects.

Taking a broad view of the subject, we observe that electricity is employed in therapeutics to accomplish certain definite ends. The clinical fact that these objects may in some cases be attained by several different methods or forms of application I have already alluded to. It is also true that others apparently, so far as we know, can only be accomplished by special apparatus and by a single method or technique. In fact, particular means are often employed to obtain definite results, because at present they appear to be the best which have yet been devised to fulfil the special conditions.

With regard to the modus medendi, or the physiological action of the agent, we may observe that electricity may be used to produce the following effects:

1. To produce local necrosis, or an eschar. Limited applications may not go so far as to cause tissue or cell destruction, and may only produce local vascular changes, or, in other words, they may act as rubefacients or counterirritants. Powerful currents, if passed through the body, will, on the contrary, abruptly terminate and abolish all physiological processes.

2. To disturb the electrical relations of the elements of nerves and muscles. This is shown by muscular contractions, produced when a nerve trunk and a voluntary muscle are brought within the influence of a current of appropriate strength. It is to be observed here that the electricity primarily gives no additional strength to the nerve or muscle, but simply calls into action energy which is already

there. However, by its power to call into play the latent energy of the muscle, it causes movements of the muscle, which in turn leads secondarily to increased blood supply and improvement in nutrition. Illustrations of this are very common, as in treating muscular paralysis.

3. To modify metabolism. Its effects in this direction are well illustrated by the Roentgen apparatus. Exposure to the *x*-rays causes local nutritive changes in the skin, the linugo hairs fall out from the operator's hands, the skin becomes glossy and thin from the atrophy of the glands, chronic ulceration may occur, which in turn may be followed by malignant disease. It has been repeatedly observed that unguarded exposure of the body to the *x*-rays causes degenerative and atrophic changes in the deeper parts, especially in the fundus of the eye and in the generative organs. In therapeutics this inhibitory and atrophic action may be skilfully directed against cancerous or other new growths. The latter having less power of resistance than normal tissue, are made to undergo retrograde change and to wither away. This is especially noticeable in epithelioma of the skin, and also in accessible organs such as the rectum and mammary gland.

4. To act as a temporary stimulant to nutritive processes, and especially to the nervous system and the circulatory apparatus. This is illustrated by the good effects upon nutrition produced by the static current and electric bath, in anemia, neurasthenia, atonic dyspepsia, chronic rheumatism, and incipient tuberculosis.

5. To accomplish certain local effects by stimulating physiological functions. This is shown in the use of electricity to increase the flow of milk from the mammary gland in the nursing woman. The use of the rectal electrode in overcoming constipation I have called attention to elsewhere. The increased function of the ovaries produced by the induced current or by the static spark is very useful in overcoming dysmenorrhea. The systematic application to the scalp causes improved nourishment of hair follicles, and not only prevents baldness, but also actually increases the growth and thickness of the hair.

6. To destroy parasites upon the surface of the body. Many infectious diseases of the skin caused by vegetable microorganisms are promptly cured by the *x*-rays. Among these I may mention tinea favosa, and tricophytina, tinea barbæ, trichorrhexis nodosa, impetigo contagiosa, acne pustulosa, pityriasis versicolor, lupus, both exedens and erythematosa, and others that will occur to you from the accounts given in the medical journals.

7. To produce electrolysis. By means of needles introduced into the skin and the passage of a suitable galvanic current, decomposition of fluids and solids occurs, and as a result there may be absorption of new growth. This is utilized in treating keloid or hypertrophied tissue of the nose or throat, and in the destruction of pigmented moles, and the removal of superfluous hair. It also has an application in the treatment of stricture of the urethra by Neumann's method.

8. To produce intense light. The method, introduced by Finsen, which has been modified by the use of the electric source of illumination, has yielded really remarkable results from its action upon lupus, and on some superficial malignant growths. The electric-light bath has been vaunted as a great restorative agent, but its utility is doubtful. In its operation the entire body is exposed to several hundred incandescent lights. In studying its effects it is difficult to separate the effects of the heat of the bulbs (which acts like a Turkish bath) from the effects of the light itself. We know that light is very irritating to the nervous system, and that the intense sunlight of tropical regions makes these unfit for a permanent residence for white races of men, as shown by Major Charles E. Woodruff of the United States Army in his recent work on the "Effects of Tropical Light on White Men." At all events, the electric-light bath does not act like the electric bath, but simply as a light and heat bath.

9. To produce high degree of heat. I need not stop to speak of the uses of the galvanocautery in surgery. It is a complete substitute for the actual cautery, and is superior to it when used as the caustic loop in removing vascular growths on the tonsils, especially in cases of hemophilia.

10. To produce magnetic effects. The electric magnetic coil is used to extract iron fragments from the eye in surgery. It is also utilized in the electric balance for detecting the location of a foreign body such as a bullet embedded in the tissues.

The use of the *x*-ray in photography and in diagnosis, as in the skiascope, does not properly come within the province of the therapeutic applications of electricity.

I have now mentioned quite a number of useful applications of electricity in medicine, and I have by no means exhausted the list, but I fear if I pursue the subject further I may exhaust your patience.

The second practical point I wish to make with regard to electricity, and with which I will close these rather desultory remarks, is this, and I regard it as a most important one:

Electricity, in most cases, is to be regarded as only an adjuvant to other treatment. While giving the special electric application we should also give appropriate remedies to act upon the glands of excretion and secretion. We should consider the state of the blood and give hematinics to increase the blood corpuscles and hemoglobin, or give antidotes to certain toxins, or eliminants to carry off gouty, rheumatic, or other pathogenic agents, in addition to our prescription of electricity. Massage, exercise in the fresh air, a proper diet, regulation of habits of the individual, all these are accessory agents and should be conjoined with the electrical treatment if we wish to obtain the best results. Such, indeed, is the intelligent medical use of this agent in the hands of the qualified physician. Without such therapeutic accessories, electricity, like massage, is very restricted in its usefulness and tends toward charlatanism.

POST-OPERATIVE GASTRIC PARALYSIS —ACUTE DILATATION OF THE STOMACH.

By W. A. BASTEDO, M.D.,

NEW YORK.

INSTRUCTOR IN MATERIA MEDICA, COLUMBIA UNIVERSITY; ASSISTANT TO ATTENDING PHYSICIAN, ST. LUKE'S HOSPITAL.

THROUGH the excellent monograph and review of forty-four collected cases by H. C. Thomson, in 1902, the attention of the profession was especially directed to the subject of acute dilatation of the stomach. Twelve of Thomson's cases were associated with surgical operations, and recently reported cases are nearly all of this type.

Of stomach dilatations, the ordinary acute postprandial type is seen not infrequently, is easily recognized, and is readily overcome by prompt

treatment; on the other hand, because of its lack of recognition, and because of its influence on the prognosis in surgical conditions, the post-operative paralytic type is of the greatest clinical importance.

I have recently seen three cases of acute dilatation of the stomach, each representing a distinct type of the affection. One was of the post-operative paralytic type; the other two were without paralysis, and were due, respectively, to the ingestion of a heavy meal in a chronically dilated stomach, and to the artificial dilatation with gas of a stomach which had an obstructed pylorus. In these three cases the precursors of the dilatation, and the condition of the stomach during the dilatation, were different.

Case I.—Miss N., aged twenty-three years, an actress, seen with Dr. Harold D. Meeker. Family history negative as to nervous or gastric trouble; one brother has tuberculosis. Ten years ago the patient had mumps, followed by severe pain in the left lower abdomen, lasting a week (oöphoritis accompanying mumps?). Never any gastric derangement, but some constipation, so that she had the habit of taking salts about once a week. Five years ago she had a gonococcus infection. On January 21, 1906, Dr. Meeker performed a curettage, and removed both tubes and one ovary. The operation lasted one hour and fifteen minutes, under gas and ether anesthesia, with Bennett inhaler. General condition throughout operation poor. After the operation her temperature was 100°, pulse 100, respiration 22. For six hours she had the usual post-ether nausea and discomfort, then complained of severe epigastric pain, and shortly afterwards vomited some yellowish fluid, with small amounts of mucus. Eight hours after operation the pain was very severe, and ⅛ grain of morphine sulphate was administered hypodermically. Temperature, 101.6°, pulse 120, respiration 22. A pint of hot saline solution given by rectum was retained. There was much retching and vomiting every ten or fifteen minutes.

At 11 P. M., nine hours after operation, the stomach was washed out, and a large quantity of bile-stained fluid removed. Following this lavage she did not vomit for two and one-half hours, and till 9 A. M., vomited only four times, though she slept but little. The next day the pain continued and the abdomen was greatly distended, so turpentine stupes were applied, and 1-80 grain of eserine sulphate was given hypodermically, and repeated an hour later, to move the bowels. A small quantity of milk, given at 9 A. M., was vomited half an hour later, with several ounces of greenish fluid. Retching continued, and she vomited four or five ounces of bile-stained fluid about every hour. At noon (temperature 101°, pulse 132, respiration 22), an enema containing turpentine, glycerin, and milk of asafetida was administered, and three hours later the bowels moved freely, with the expulsion of some gas. In spite of this the distention and the vomiting continued. At 4 P. M., lavage, and the administration of six ounces of peptonized milk through the tube, gave rest for three hours. At 6 P. M. she was given a nutrient enema, and at 7 P. M. the vomiting began again.

At 7:30 P. M. I saw her for the first time. As had been noted by Dr. Meeker, there did not seem to be any marked tension in the region of the abdominal incision above the symphysis, but there was great ballooning higher up. On pressure two inches below the umbilicus there was no pain and no marked resistance, but, on pressing above the navel, the pain was intense and the resistance pronounced. The vomiting was not expulsive; it was preceded by much retching, and the fluid seemed to flow out of the mouth without great effort. A stomach tube was passed, and a large quantity of rather grumous, deep-green fluid was removed. It contained a few particles of orange, which we discovered had been surreptitiously given by a friend just before the operation, and was without free hydrochloric acid, though acid in reaction. Lavage was continued for ten minutes, and then six ounces of peptonized milk were given through the tube. The pulse was 140, and feeble. She did not vomit again for four hours, and then the vomitus was almost free from milk.

The diagnosis of acute paralytic dilatation of the stomach having been made, the patient was put on hypodermics of strychnine sulphate gr. 1-30 every three hours, and was to be given by mouth one dram of chloroform water every two hours, each dose to be followed in five minutes by two drams of peptonized milk. She was to have a nutrient enema twice a day, and lavage twice a day, six ounces of peptonized milk to be left in the stomach after each lavage. Only twice again did the patient vomit, each time about four hours after lavage, a greenish fluid, containing a few milk remnants.

By the next evening the distention was much less and the patient was comfortable, so the amount of peptonized milk to follow the chloroform water was increased to half an ounce. The maximum of temperature for the day was 100.5°, of pulse 120, of respiration 22. The following day, the third after operation, the maximum temperature was 99.5°, pulse 113, respiration 20.

The amount of peptonized milk was steadily increased, and three days later the patient was getting three ounces every three hours. On January 30, nine days after the operation, the chloroform water, lavage, and nutrient enemas were discontinued, and the diet made plain milk. From this time she rapidly graduated to light diet, and then to modified regular diet, without further disturbance.

Case II.—Miss A. S., aged forty years, a cook. Was summoned to her in great haste, and found her lying on the floor, upon which she had collapsed a few minutes previously. The story was that, while at dinner, half an hour earlier, and after having eaten heartily of boiled ham, cabbage, etc., she had felt faint and dizzy, and had complained of pain in her stomach. She had belched some wind and tried to vomit, but could not; and presently, while on her way to a couch, had collapsed on the floor, where I found her. On my arrival her expression was anxious, she seemed unable to speak, and gasped for breath, her skin was cold, cyanotic, and sweating, and her pulse rapid and feeble. The abdominal wall was fat, but there was marked ballooning of the whole abdomen, so that it was tense, like a drum. The navel was at the most prominent part of the swelling. Having only a pocket case with me, I hastily administered a hypodermic of 1-10 grain of apomorphine, and, mixing some rhubarb and soda tablets with water, gave this by mouth. In a moment she belched much gas, then began to heave, and presently brought up an immense quantity of thick fermenting liquid, which contained large chunks of ham, cabbage, potatoes, etc. The vomitus filled a good-sized basin, and

smelt strongly of fermentation. The relief was almost instantaneous, and in a few minutes her pulse was strong and below 100, her breathing was easy, and with our assistance she got into bed. I saw her the next morning, and, though still a bit weak, she seemed to have recovered from the attack, and complained of hunger. She told me then that she had suffered much from digestive trouble, was always bloated, frequently belched gas, and now and then would vomit food that she had eaten twelve or fifteen hours before. Her teeth were in bad condition, and her stomach percussed to about two inches below the umbilicus. I did not see her again.

Case III.—Mrs. R. S., aged fifty years, housewife, was referred to me in the Department of Applied Therapeutics at the Vanderbilt Clinic, as a case with disease of the digestive organs. Her chief complaints were: belching of large quantities of gas, occasional vomiting of sour fermenting food, and the loss in weight of 60 pounds in six months. On inspection there was seen constant moderate peristalsis, beginning at the left free border of the ribs and passing at first downward, then to the right below the umbilicus. Just to the right of the mid line, and from two to three inches below the navel, was an area of intermittent vibratory palpation, with a loud, harsh auscultatory gurgle, and an indefinite mass felt uncertainly through a tense rectus muscle. The test breakfast gave a large quantity of stomach contents, with a total acidity of 44, no free HCl, some organic acid, no lactic acid, rennet ferment very active. The stool gave a strong reaction for occult blood. This was a case of pyloric stenosis, presumably carcinomatous, with apparently a large stomach displaced downwards.

In order to note the influence of inflation on the position and palpability of the tumor, and in the belief that the stomach capacity was greater than normal, unusual (and unjustifiable) amounts of sodium bicarbonate and tartaric acid were administered. Almost instantly the patient cried out, and fell back in collapse, and the stomach was seen tightly blown up. The patient's face was deathly pale, the pulse almost imperceptible. A stomach tube was hurriedly passed, and large quantities of frothy fluid escaped, with immediate relief to the patient. Half an hour later she walked home without assistance. She refused operation.

These three cases, then, may be summarized as follows: In Case I. the acute dilatation was due to paralysis of the stomach, pylorus, and probably part of the duodenum, a condition which quickly followed an operation for the removal of both tubes and one ovary. The retching and the bile-stained stomach contents indicate that the pylorus was open, and was presumably involved in the paralysis. The bowels were not paralyzed, as they moved freely under treatment. There was no history of any previous stomach derangement.

Noteworthy in this case, as in some of the other reported cases, is the large amount of secretion, in appearance like that obtained from the fasting stomach in cases of gastrosuccorrhea, with the addition of bile; and the fact that vomiting does not seem to notably lessen the distention, or belching bring forth any large quantity of gas.

Would it not be better to employ the term "Gastric Paralysis" for these post-operative cases, as it is directly analagous with the much-used term "Intestinal Paralysis," and is more indicative of the actual condition than is the name "Acute Dilatation?" Besides, in these cases, the dilatation is undoubtedly only incidental to the paralysis.

In Case II. the acute dilatation supervened upon a chronic dilatation. The immediate etiological factor was an abnormally large meal of material so imperfectly masticated that it would not pass the pylorus, ingested into a stomach which already contained an accumulation of fermenting contents. The pylorus was active, and, probably owing to the iritating fermenting stomach contents, tightly closed; the stomach wall still retained its muscular power; and the nerves and centers were intact and functional, as shown by the prompt response to the hypodermic of apomorphine. Surely in this case there was acute dilation *without* paralysis.

In Case III. the acute dilatation was due to the sudden generation of carbon dioxide gas, in quantity greater than the stomach could hold, its escape into the intestine being prevented by a pyloric obstruction. The muscle of the stomach wall was strong and active, both before and after the momentary overdistention of the viscus, and there was evidently no paralysis. I have seen one other case of this kind in a woman with jejunal obstruction.

Acute dilatation of the stomach, then, may be paralytic or nonparalytic, and post-operative abdominal distention may be due to gastric paralysis, as well as to intestinal paralysis.

THE EXCEEDING IMPORTANCE OF A CLEAR UNDERSTANDING OF THE VASOMOTORS AND THE UTILIZATION OF THEIR FUNCTION TO GET BEST THERAPEUTIC RESULTS.

By W. C. ABBOTT, M D.,

CHICAGO, ILL.

Whatever may be the anatomical structure that affords the phenomena we term vasomotor, it is certain that perturbations of vasomotor equilibrium form the earliest evidences of disease in the vast majority of maladies. So delicate is the adjustment of the governing apparatus that the first evidence of approaching disease is almost invariably to be displayed in alterations in the vascular tension of some or other area. Let this be due to the advent of an invading swarm of bacteria, or to the presence of a chemic irritant in the blood conveyed to the part, the first response to any abnormal irritation is to be seen in an alteration of the caliber of some part of the circulatory tract; in fact, such a change is usually requisite for the production of pathological lesions that are recognizable by microscopic investigation.

In venules, arterioles, or capillaries, or in all three, we have first either a condition of spasm by which the vessels are contracted and the blood is forced out into the general circulation, or a state of paresis, the vessels dilated and containing more than the normal quantity of blood which leaks into the area of low pressure from the general circulatory reservoir. Here commences the anatomy of disease—and that frightfully neglected process, the physiology of disease. Too much attention and too much importance have been given to the dead tissues, too little to the aberrations from normality displayed by the still living organs and acting functions. It is with liv-

ing, functionating tissues that we have to deal; with pathological processes while still active, in bodies not yet devitalized, and not with the final end-results of these processes, in bodies that have succumbed. If a patient is still alive to-day, he should have enough vitality to keep him living for a succession of to-morrows, provided we can successfully cope with his malady and prevent its making further progress. We may, then, take up the question of eradicating the malady, which is another matter.

The physician who accustoms himself to study the conditions presented by the vasomotors soon learns to detect the earlier perturbations, to recognize local "jangles," and to apply his remedies before the difficulty has progressed beyond the simple disorder of tonicity-excess or -deficiency. It may not be easy to give a nosological designation to these cases, and the physician may have his own opinion as to whether in dissipating the disease and restoring circulatory equilibrium he has aborted a pneumonia or jugulated any other affection; but he knows that just such cases let alone do develop into maladies that can, without the slightest difficulty, be recognized and classified, and that in their fully developed forms may really verify the pessimistic dictum—there is no treatment that cures.

How many diseases of the body politic could be cured in their incipiency by a little, a very little common sense? How many destructive wars could have been checked at the outset if only the principals had had a little more mutual consideration? How many floods could have been prevented had there but been a boy along to stop the beginning crevasse in the levee with a chunk of sod? Even the case of tetanus or of rabies might have been jugulated by a prompt excision of the virulent microbic colony at the start, to say nothing of the ease with which most acute affections may be jugulated. Innumerable similar instances could be adduced showing the efficacy of well-placed intervention at the beginning of morbid processes.

It will be objected that this treatment of a symptom is unscientific in that it does not strike at the cause of the illness, but is aimed at a result, and a superficial one at that. This is another of those illogical jumpings at conclusions without warrant which we have so often cited. How do you know the treatment that removes a symptom does not remove its cause? Is it not *prima facie* evidence that it does so when the results disappear? Take any symptom-complex that presents itself, it evidently depends on some pathological aberration, but just what we are, in the vast majority of cases, unable to say. But whatever it may be, it is a fair inference that the treatment that restores to health, or that causes the disappearance of that symptom, must remove the cause—otherwise, if the cause is still active, why does not the symptom remain? This, of course, does not aply to the smothering of pain by morphine or of fever by cold, although there are not wanting those who claim actual curative action from these measures, and we admit the possibility.

There is a certain degree of fetich worship in regard to this "cause" of disease. A dagger inserted in the heart causes a wound—removal of the dagger hardly cures it. A swarm of microorganisms descends on a toxic patch of tissue in the lungs—removal of the intruders does not necessarily leave the lung intact. There is failure to distinguish between the original cause of a malady and the results of that malady. Each demands treatment; each responds in a different manner to therapy. How long we bungled over cases of cerebral syphilis before we appreciated this truth, and learned that we must intervene as quickly and as powerfully as possible in order to prevent damage to the delicate tissues which not all the mercury out of Spain could restore! Remove the causes of disease, to be sure; treat the cause whenever you find it still acting, but don't limit your therapeutic activity to that one method or argue that there is no room for any other indication.

It is the all but universal presence of vasomotor disequilibrium in the whole wide field of clinical medicine that compels such constant reference to the four great vasomotor remedies in the practice of our art—aconitin, veratrin, digitalin, and strychnine. These, singly or combined, form an essential part of the therapy of so many cases of so many maladies, that they, above all other remedies, are constantly mentioned in my work. That the causal indication is not neglected is shown by the interminable injunction to first clear the bowels and disinfect them, and to keep doing so, since observation has shown with what frequency the absorption of toxins from the alimentary canal coincides with the occurrence of disease in limited areas where the vital resistance is presumably lowest.

Whether autoinfection occasions disease directly from chemical action or, by still further lowering resistance, opens the door to invading microbes makes little difference—the indication for establishing intestinal exosmosis is similarly almost universal. The man who appreciates the importance of these two pathological principles, the fact of autotoxemia and the constant presence of vasomotor instability, has a broad foundation on which to build his practice. To this he can at every step add something—he never has to unlearn these two lessons. Making these the basis, never neglecting them in any case, we find that every patient displays indications for something more, but never with a frequency comparable with that of these two.

We constantly find the necessity of referring back to the newer works on physiology, and we glean every scrap of pathological information we can find, for we cannot afford to be ignorant of a single fact that may explain our cases. So also we must possess hundreds of remedial agents, although nine-tenths of our work may be done with a score. But it is in the remaining tenth that we find the greatest pleasures of the practice of medicine, when by the exhibition of some definite active principle that has not been needed for years we meet an indication that has not presented in that period, but for which we have had the remedy waiting.

I beg my readers to pardon me for the importunity with which I beseech them to consider these truths. I cannot help it; I do so want them to know of these exquisitely differentiated remedies that I cannot help being urgent. And, knowing these things so well, how important they are for the profession and for suffering humanity, when I find that one does not really know there is a difference between hyoscine and atropine I am ready to lie down and die.

Habitual Constipation and Latent Inflammations of the Peritoneum.—R. Romme declares that an individual who suffers from habitual constipation may have a latent and unrecognized lesion of the appendix, of the adnexa, of the gall-bladder, or of some other abdominal organ. The etiological rôle of habitual constipation in appendicitis is well known. Villard to a certain extent reverses the terms of this problem, and in place of considering constipation as an efficient cause of appendicitis he thinks rather that obstinate constipation is often the result of a latent appendicitis more or less unrecognized.—*La Presse Médicale.*

SYPHILIS OF THE NASAL FOSSÆ.

By ALBERT BARDES, M.D.,

NEW YORK.

LECTURER ON DISEASES OF THE NOSE AND THROAT AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL; SURGEON AT THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

It is apparent to every physician who labors in the clinics of New York that syphilitic affections are becoming increasingly common, and in the opinion of many legislation will have to be resorted to in order to check the progress of this loathsome disease, the ravages of which are more pronounced in the nose than in any other organ.

The tertiary lesions are those that the rhinologist is usually called upon to treat, these producing the characteristic ulceration and necrosis that is so injurious to the functions of the nose, and so disfiguring to its shape. The primary lesion—the chancre—is seldom seen in the nose, and when it does occur it is usually in the vestibule, which is accessible to infection by the finger nail. Secondary lesions are frequently seen in the nose, in the form of mucous and erythematous patches. They appear from two to twelve months after infection, in groups, being separated from the healthy surface by a distinct outline. These lesions are the most contagious in syphilis, more virulent even than the chancre itself. Physicians should bear this in mind, and patients should be apprised of it, so that the chances of infection may be minimized. Secretion obtained from secondary lesions is capable of producing syphilis by inoculation, and the blood of an individual with secondary lesions is fatal to monkeys. The true tertiary lesions, the gumma and the ulcer, are neither contagious nor inoculable. What is regarded as the specific organism of syphilis, the spirochete of Hoffmann, is constantly present in all secondary lesions, in primary sores, and in syphilitic new-born infants. It should be observed that in the tertiary stage there often occurs what appears to be a mucous patch. Closer examination will show that it is in reality an ulcer.

In the nose, secondary lesions are frequently overlooked on account of the mildness of the symptoms—merely those of a cold in the head—and it is not until patches are also seen in the throat that the true condition is brought to light. Whenever a patient complains of symptoms of rhinitis, accompanied by loss of hair, nocturnal headaches, swelling of the glands of the neck, and other signs of syphilis, it is evident that the rhinitis is of syphilitic origin. Among young children syphilitic rhinitis occurs oftener than is generally believed, but in many instances the condition is not recognized until the destructive changes are well under way and are irreparable. It differs from a simple rhinitis in that the symptoms are severe and persistent, and show no signs of being self-limited. A child with this condition has that peculiar obstructed nasal respiration known as snuffles, which greatly interferes with its nursing, and the nose constantly secretes a watery mucus, which causes excoriations and sores about the orifices of the nose and mouth. The harsh, brassy cry of many of these infants is an evidence that the larynx, too, has been invaded. The general appearance of a syphilitic infant is quite characteristic. The shrunken body, the pale, colorless, and mummified face, and other evidences of malnutrition, stand out glaringly. Inherited syphilis resembles the acquired form in its course and general manifestations, and frequently it remains quiescent until the patient has reached adolescence. In most instances syphilis in infants runs its course rapidly, destructive changes occurring, perhaps, from six to twelve months after infection. Fortunately, the reparative process in infants is such that the nose seldom becomes deformed through the ravages of the disease.

In adults, the nose is the place of predilection for the destructive lesions, which appear from two to ten years after the chancre. Some observers maintain that tertiary lesions are but relapses or recrudescences of secondary lesions, but their noncontagiousness and noninoculability oppose this view. In certain forms of syphilis, such as the malignant and the Asiatic, the disease passes through the cycle of changes with great rapidity, and destructive lesions may appear as early as six months after infection. Not infrequently the exciting cause of an intranasal lesion is traumatism, which stirs into activity a latent syphilitic process. Whether destruction of tissue takes place slowly or rapidly, syphilitic lesions in the nose present certain distinguishing features that to the experienced eye are unmistakable evidences of the disease.

The gumma is the lesion that precedes all destructive changes in the nose, although it may assume a different form and run a different course in different individuals. The round tumor-like variety, so common in other parts of the body, is seldom seen in the nose, and when it does appear it is usually upon the septum, resembling a deflection. A gumma in the nose is so well protected and free from irritating influences that it usually develops insidiously, and may not break down until the lapse of months and even years. Pathologically considered, a gumma consists of an infiltration of small, round cells or inflammatory corpuscles, involving soft as well as dense structure. A progressive gumma undergoes a number of changes before it disappears. First it becomes infiltrated, then it softens and degenerates, then it ulcerates, and, lastly, it becomes firmly cicatrized. The points of predilection in the nose are the septum, the turbinates, and the nasal floor, in the order named. The gumma may start from the surface, and secondarily invade the deeper parts, or else it may begin in the interior of the bone or cartilage, and break through the overlying structures. In the nose more frequently than elsewhere a gumma breaks down, and destruction occurs without the patient's knowledge, and often it is not until breathing is interfered with, or the odor becomes offensive, that the patient becomes aware of its presence. A gumma in the nose resembles a carbuncle, being elevated, purple in color, and separated from the surrounding surface by a distinct outline. Touched with the probe, it is firm and insensitive, later on becoming soft and taking on a high color, like a maturing abscess. At this stage it pits upon pressure, is sensitive and vascular, and secretes a watery mucus. As soon as it has undergone complete degeneration, it disintegrates and becomes an ulcer, and this ulcer enlarges until the entire infiltrated area is uncovered. Intranasal lesions, like the deep syphilodermata, are restricted and localized, adjacent parts not becoming involved until the already diseased area has first been destroyed.

As said before, the most common site of an intranasal gumma is on the septum, and a lesion

here is usually of a larger size than when it occurs elsewhere in the nose. The lesion usually starts in the bony septum and creeps forward until the cartilage is implicated and destroyed, eventually leaving a clean, round hole in the septum that looks as if it were punched out. A perforation in the lower part of the septum, involving either a part of the bone or cartilage, produces no deformity. It is only when the entire cartilage, or else the supporting plate of bone is destroyed that the nasal arch loses its support and causes the nose to sink in. It is fortunate that the nasal arch resists destruction as well as it does, otherwise nasal deformity would occur more often.

A lesion in the upper part of the nasal fossa is far more injurious than one in the lower, owing to the fact that an ulcer above is soon covered with a dense scab, which seals the surface and prevents the escape of the morbid secretion. This, in turn, attacks the deeper parts and undermines the nasal skeleton. This does not occur in the lower part of the nose, owing to the facility with which foreign substances are washed away by the abundant supply of nasal mucus. Another favorite place for a gumma is upon the inferior turbinate bone. Such a lesion is difficult to detect, because it is usually situated well back in the nasal chamber, and resembles a turbinal hypertrophy. A lesion upon the turbinate is often accompanied by distressing symptoms. There is a severe nocturnal headache and a dull, aching pain in the side of the face that may last for months. As soon as the gumma breaks down, the pain and headache subside, and a purulent discharge makes its appearance. A syphilitic deposit upon the floor of the nose may exist for a long time without being detected. Frequently the first intimation that we have of a deposit in this region is a hard swelling upon the roof of the mouth, which soon breaks down and exposes to view a sequestrum of dead bone. This is soon detached and cast off, leaving a hole in the palate which greatly interferes with speaking and with eating. It frequently happens that while destruction is going on in one part of the nose, cicatrization is taking place in another. Occasionally the diseased bone, instead of becoming necrotic, becomes dense and eburnated, and acts as an obstruction. The excruciating pain that is sometimes complained of in syphilitic affections of the nose, is usually due to the involvement of one of the large nerves that pass through the numerous foramina in the nose. Rarely it is due to the extension of the syphilitic process to the meninges.

A typical syphilitic ulcer in the nose can scarcely be mistaken. It is cup-shaped, the surface is covered with a thick, firmly attached crust, and its edges are elevated and undermined. In some instances the destructive process appears to be self-limited, and, after a certain amount of tissue has been destroyed, repair begins. In other cases there appears to be no limit to the destruction. As soon as denudation, and consequent necrosis, takes place, there occurs that unmistakable and disagreeable odor known as syphilitic ozena; a smell like that of crushed bedbugs, that clings to the patient, and appears to saturate his very clothing. In this disease, as in most other forms of chronic rhinitis, the bad smell is seldom apparent to the patient, or at least not in the same degree as to those about him. This is partly because he has insensibly grown accustomed to the odor, and partly owing to the impaired sensibility of the olfactory membrane. Decomposition and crust formation are present in all forms of intranasal ulceration, and the fetor that accompanies destruction of bone is as constantly present in simple forms of atrophic rhinitis, in which the destruction is molecular, as in syphilis, in which it is *en masse*. The discharge of offensive crusts, mixed with blood and pus, from the nose is characteristic of a syphilitic ulcer. Often the discharge contains pieces of foul-smelling bone that have a worm-eaten appearance, the dislodgment of which may produce severe, and even dangerous hemorrhage. After the activity of the syphilitic process has abated and the lesions have healed, the formation of dense scar tissue takes place. Except a deep burn, no lesion is followed by greater cicatricial contraction than a deep syphilitic ulcer. The scars have the same radiate appearance of syphilitic scars elsewhere, being dense, glistening, and tense. Where the destruction is extensive, the resulting contraction may be so great as to lead to troublesome stenosis and marked deformity.

The most noticeable sequence of syphilitic intranasal ulceration is the repulsive and highly disfiguring flattening known as saddle-back nose. The practically incurable nature of this deformity, and the insidious manner of its development, makes the timely treatment of all syphilitic affections of the nose a matter of the greatest importance. Syphilitic nasal deformities are of three kinds: Those in which the septum is destroyed and the nose is sunken; those in which some part of the external nose is destroyed, and those in which both the former and latter conditions are combined. Unusual deformities are those in which the lateral walls, as well as the septum, are destroyed, so that the nose is completely flattened and its profile is not seen above the face. In extreme destruction there is atrophy of the soft parts, and the tip of the nose is turned up and greatly reduced in size, giving the face an ape-like appearance.

The treatment of syphilitic affections of the nose is both local and general. The constitutional treatment is that of the disease in general, and continuous rather than intermittent medication is advised until the lesions are healed. Although the lesions are usually of the tertiary variety, in which potassium iodide is indicated, they are more promptly controlled by the mixed treatment. In my experience most lesions can be brought under perfect control by internal medication, but, in exceptional cases, hypodermic injections of mercury, or inunctions of the same drug, are necessary to check the progress of the disease. Inunctions are particularly applicable in children, and they may be supplemented with the administration of the syrup of the iodide of iron. Adults can begin with 5 grains of potassium iodide and 1-5 grain of the protoiodide of mercury after each meal, with plenty of milk, gradually increasing the dose until the lesions have disappeared. Then the dose can be reduced and given intermittently. Just how long antisyphilitic medication should be given in order to confer immunity has not yet been determined, but it is wise to continue treatment for at least two years after the ulcers have healed. Local treatment consists in cleanliness, the removal of necrotic bone, stimulation of the ulcer, and prevention of adhesions and deformity.

Few lesions are more amenable to medication

than those of syphilis, providing it is begun before the destructive changes are well under way. It is a good plan to give antisyphilitic remedies for all suspicious intranasal lesions, for not infrequently a tumor or an ulcer, supposedly malignant or tuberculous, disappears entirely upon the administration of mixed treatment.

No attempt should be made to correct a deformity due to syphilis until the patient has been subjected to a course of medication covering a period of two years, otherwise the surgical procedure may excite irritation and ulceration.

A nasal deformity can be greatly improved by subcutaneous injections of paraffine. It is better to inject a small amount at different sittings than to inject too much at one time, thus avoiding sloughing and other mishaps. Artificial bridges and supports have been tried and found wanting. For a perforated palate, a dental plate of hard rubber gives the most satisfaction.

OBLITERATIVE ENDARTERITIS OF FEMORAL DISTRIBUTION WITH GANGRENE OF THE FEET.

By EUGENE H. EISING, M.D.,

NEW YORK.

ADJUNCT SURGEON SYDENHAM HOSPITAL; SURGEON GOOD SAMARITAN DISPENSARY.

Although Jaesche in 1865, and Burrow in 1867, had described cases of proliferative changes in the intima of arteries with subsequent obliteration, it remained for Friedlander in 1876 to describe the lesion and to recognize it as a pathological entity. Winiwater three years later added to the scanty literature upon this topic a detailed description of obliterative endarteritis with gangrene of the feet. Since then there have been from time to time contributions in German, French, Russian, and English. I have failed to find any word in American literature upon this subject. If the last had been said, and this particular chapter of disease had thereby been closed, any attempt to add a word would be futile. The conditions, however, are not such; nowhere in the realm of medical science are the etiological factors more obscure. The condition is not recognized as a clinical entity; the textbooks barely give it recognition, and much confusion reigns in cases thus far reported.

Obliterative endarterial changes in the femoral distribution present a symptom complex and clinical picture truly distinctive, and quite as characteristic as similar changes occurring in the brain. The disease is slow in progress, terminating in gangrene of distal parts, and is usually confused with Raynaud's Disease and erythromelagia. The importance of the intima in physiological and pathological processes must be distinctly recognized. The prime function of an artery is to maintain a patent channel for the blood stream, and this depends upon the integrity of the intima. Physiological obliteration of blood-vessels as occurs in obsolete channels, such as the ductus arteriosus and the umbilical vessels, is accomplished almost entirely by a proliferation of the endothelium of the intima. A similar process occurs in the proximal ends of arteries following amputations. Under pathological conditions we recognize primary changes in arteries occurring in the intima. The only primary change in the middle coat is simple degeneration—calcification. Primary change does not occur in the adventitia. The intima is, in fact, the essential part of an artery; the middle and adventitious coats are mechanical necessities enabling it to fulfill its function. The endothelium of the intima responds to irritation similarly to endothelium elsewhere, resulting in proliferation of new cells. Owing to the resistant elastic lamina of the middle and outer coats, proliferation is directed centripetally, and, in consequence, the lumen of the vessel is encroached upon. According to Foster, the blood flowing through the blood-vessels is in a state of unstable equilibrium, which may at any moment be upset with clotting as a result. It would seem that the altered relationship between diseased intima and blood, or rather between diseased intima and fibrin ferment, maintains the fluidity of the blood in a less stable state. Endothelial proliferation may be only fairly advanced in an artery of the dimensions of the femoral or popliteal, the lumen of which may be entirely choked by a canalized fibrin thrombus. The thrombus can be dragged out for some inches through the cut end of the vessel. The canalization may not be sufficiently large to admit the passage of a straw. This variety of thrombus is the result of a concentric lamellation of fibrin upon the inner coat of an artery. The thrombus is long and tubular, and is not firmly adherent to the vessel wall. It receives no nutrient vessels from the wall of the artery. Endarterial obliteration, as described, is therefore the result of the combined action of a slow neoplastic agency occurring in the intima, together with thrombus formation by fibrin deposit. The disease under discussion is characterized by the slow lamellar thrombotic process, and corresponds to the slow advances of the clinical phenomena. During the course of the disease, however, thrombosis by clot may supervene and invite a more acute gangrenous process.

I have the good fortune of retaining under observation one instance of this disease for a period covering five years, and of a second for a much shorter time.

Case I.—I. G., large florid male, Russian Jew, age forty-two years. Peddler by occupation. Denies any acquired or inherited specific taint. Uses alcohol and tobacco moderately. Attributes present condition to no known cause, other than to climatic exposure. Seven years ago began to have pain in left foot and toes. Pain was of burning character, and was nearly constant. There were occasional anginal attacks in the muscles of the leg. Pain was not aggravated by moderate pressure. The foot and toes were red in color, but presented no alteration upon change of posture. Cutaneous sensibilities to temperature and pain were normal. Medicines, hot-air treatment, and baths were without avail, under which regimen he remained for two years.

At the end of this time a gangrenous ulceration appeared upon the great toe, and was soon followed by a similar area upon the toe adjacent. The symptoms enumerated above persisted. It was noted that at this time there was no dorsalis pedis pulse to be felt upon that side. No note was made of other pulses in that extremity. The foot was amputated through the ankle. During a period of nine months subsequently the wound refused to heal. The leg was then amputated above the knee, and from the proximal stump of the popliteal artery was drawn a long, white,

canalized thrombus three inches in length. The wound was closed, and healing ensued.

At the present time, five years after the amputation through the thigh, he again complains of great pain in the stump, together with a deep cyanosis. He was free from pain until a year ago. There is no pulsation in the femoral artery of that side. An attempt was made to feel the external iliac pulse per rectum, but the vessel could not be reached.

The patient now, and for the past year, has had pains of similar character in the right foot and toes. There is little or no change of color, and no change with foot dependent. The dorsalis pedis pulse on the right side is absent. The femoral pulse is palpable, and apparently not diminished. There is no other determinable vascular disease. There is neither albumin nor sugar in the urine, nor has there at any time been hematuria. Unfortunately, there was no further examination made of the amputated extremity.

Case II.—A. G. Tall, slender male. Russian Jew, age twenty-eight years. Peddler by occupation since landing in this country two years ago. Previous to that time had been a farmer. Parents living and healthy, as are also four brothers and three sisters. Smokes moderately, and has never used alcohol. Has never had syphilis. Has always been well in recent years until onset of present complaint. About one and a half years ago began to have anginal attacks in calf of left leg; the pain would extend to the foot and toes, and sometimes would last for several days without cessation. There was nothing to be seen upon the leg or foot to account for the pain, which was deep-seated, and difficult to locate exactly. It was described as of a boring and burning character. Various salves and baths were prescribed for the pain without avail.

For seven or eight months the pain has diminished in the leg, but persists, and is worse in the foot and toes. During the past four months the pain has been extreme and constant in the large toe and toe adjacent. An ulceration has developed upon the great toe, and the distal three-quarters of the foot has assumed a dull red color. This color persists in horizontal and pendant positions. The ulceration upon the great toe is upon the under inner surface, and towards the tip. It refuses to granulate. There is no pulsation in the dorsalis pedis artery on this side, nor can pulsation be felt in the popliteal with leg flexed at right angles. The femoral pulse is good.

The reflexes are normal, as are also the cutaneous sensibilities to pain, touch, and temperature. No blood pressure estimation could be made, owing to the absence of a pulse at the periphery. Otherwise the patient's general condition is good. There is no further evidence of arterial change.

The patient was told the serious nature of his apparently slight affection, and was advised to remain in the horizontal position. He was given nitorglycerin and iodide of potassium. In the course of ten days of care in hospital his pain was very severe, and had to be controlled by opiates. Meanwhile, the ulceration upon the great toe extended and became foul, and the adjacent toe became first cyanosed, and then black. Both toes were amputated. During the course of the succeeding two and a half weeks the wound sloughed, the edges became black for a considerable distance, and a foul, yellowish discharge exuded from the wound. The leg was amputated above the knee. The wound healed by primary union.

Examination of the amputated extremity revealed the dorsalis pedis artery entirely obliterated, represented by a fibrous strand. No canal was demonstrable. The posterior tibial contained almost throughout its length a canalized lamellated thrombus. With the artery laid open this thrombus was found not particularly adherent, and could be raised from the vessel wall at any point. The vessel wall itself was not much altered. The popliteal artery itself, up to the level of the amputation, was also occupied by thrombus, but differing materially from that in the posterior tibial artery. This thrombus was evidently formed by blood clot. It was reddish in color, it was not canalized, and was also only lightly adherent to vessel wall. The thrombus was partly organized.

The symptomatology of this condition is so well demonstrated in the foregoing cases that little need be added. The likelihood of error seems to be to confuse this disease with Raynaud's disease, but with little care both the symptoms and course of the disease will be found to be entirely different. Michels and Weber have recently reported a case almost identical with my first. Their report includes a careful study of the microscopic findings. The cases reported by Arkwright and Dunlop, if at all instances of this disease, are complicated. The question of etiology is still obscure and speculative. Friedlander considers injury and exposure to cold important factors. Wwedensky believed there was an underlying neuritis, upon which is imposed an arteritis. Sternberg assumes injuries applied to a weakened and depressed vascular system, and Hollis suggests that by the repeated impact of foreign particles against the sides of a small artery, a state of irritation or "molecular unrest" is established within certain endothelial cells. None of these theories quite satisfies the conditions. It would seem that if the cause were endarterial, such as a toxin conveyed by the blood stream, its action would not be selective to a certain arterial distribution. If there be extravascular agencies their nature still remains obscure. The two cases cited above would rather suggest that the disease in its onset is peripheral, inasmuch as the obliteration was farthest advanced in the distal parts.

The disease is slowly progressive, and is not cured by amputation, as is evidenced by the recurrence in the amputation stump of Case I. Wwedensky believed the condition to occur only in Russian and Polish Jews. Michels and Weber also comment upon this fact, the case reported by them having occurred also in that race. My two cases are both Russian Jews. A. Pearce Gould, in The Second Lettsomian Lecture, cites several cases, but no mention is made of this fact. I have failed to find anything racial that might predispose Jews to arterial changes. The ergot in the use of rye bread seems to play no rôle. It is to be hoped that modern research in artery-vein anastomosis may find a fruitful application in this disease.

THE USE OF OXYGEN IN ASPHYXIA NEONATORUM.

By C. D. SPIVAK, M.D.,

DENVER, COLO.

Quite frequently it happens that while the obstetrician is busy in checking a postpartum hemorrhage, or in repairing a lacerated perineum, it falls to the lot of the attending nurse to look after the needs of the neonatus. In cases of asphyxia, she even assumes the rôle of a goddess in actually "blowing into his nostrils the breath of life." Under the guidance of the attending physician, many a nurse has resuscitated an apparently dead child by the various methods, mechanical, medicinal, etc., known to the modern practitioner.

At the maternity department of St. Luke's Hospital, Denver, in desperate cases of asphyxia neonatorum, a novel method has been adopted at the independent suggestion of two nurses, each unknown to the other. In one case, after having exhausted all his skill, resources, and strength, the attending physician concluded that the child was beyond human aid, and left the hospital in despair. The attending nurse cast her eye on the tank of oxygen which was standing in the corner of the room, and decided to make an experiment of her own, even at the risk of incurring the displeasure of her superior. She turned on a stream of oxygen into the nostrils of the baby, and was overawed to see the infant take its first breath. On the following day the attending physician was amazed to find a live baby in the arms of its mother.

The other nurse, in a similar case, timidly suggested to another attending physician, after he had thrown up the sponge, to use a few whiffs of oxygen. He did not protest against her audacity to express an opinion in his august presence, but grasped at the opportunity of trying a novel procedure. He was repaid by having saved a human life, and by the gratitude which shone in the eyes of the parturient and nurse.

Having obtained the permission of the physicians and nurses to publish the above, and after consulting the recent text-books on obstetrics, the available current literature, and several prominent obstetricians without finding any record of the use of oxygen in asphyxia neonatorum in this country, I concluded that the subject deserved to be brought to the attention of the medical profession for the purpose of further research, discussion, and experiment.

I hope I shall not be accused of mere gallantry if I mention the names of the two nurses who suggested the new method—Miss Marguerite Bullene, day head-nurse, and Mrs. Oca Cushman, night head-nurse of St. Luke's Hospital. Even should future research not accord to them the honor of priority, they deserve credit for having revived an old method of resuscitating the apparently dead newborn in the city of Denver, where this method was certainly unknown.

Has oxygen ever been used, or its use suggested, in resuscitation of the drowned?

142 Court Place.

Obstruction of the Biliary Passages.—Delbet does not think that the hypotheses which have been offered to explain the lesions of the gall-bladder are sufficiently convincing, for this is a very complex subject. The causes which must be investigated are the nature of the obstruction, the condition of inflammation of the biliary passages, and the location of the obstruction. The last factor plays a very important rôle. Supporting his point of view, Delbet refers to a case of cancer of the pancreas which, by compressing the ductus communis choledochus, brought about atrophy of the gall-bladder. The nature and the seat of the obstruction, however, are not the only conditions to be considered; account must be taken of the bladder wall. Not only does inflammation cause retraction of the gall-bladder, but it also brings about distention. Inflammation of the mucosa may bring about a hypersecretion and lead to that condition which is wrongly called dropsy of the gall-bladder. Inflammation of the other layers bring about more easily a sclerosis. A complicating factor is that in many of these cases there are two successive stages, a temporary period of dilatation and another period of definite retraction.—*La Tribune Médicale.*

Inflammation and Peritonitis Considered as Physiological Processes.—John D. Malcolm, in the conclusion of his paper on this subject, says that it seems probable that an obvious and definite aseptic peritonitis is a not uncommon condition; that aseptic inflammation may be described as consisting of the local physiological changes in and around damaged tissues which are brought about by an injury, and which increase in activity for not more than three days after the injurious action ceases—the object of this increased physiological activity being the removal by absorption, without obvious loss of tissue, or the demarcation, with a view to separation, of those parts which have been so damaged that their period of usefulness to the animal economy has ended. The result in some cases, however, is a revival of tissues which have been deprived of their blood supply. Septic inflammation may be described as consisting of the local physiological changes in and around damaged parts which are brought about by an injury and by the presence of irritating microorganisms acting on the damaged and adjacent tissues, or which are brought about by the action of such microorganisms on undamaged tissues—these changes continuing and varying in activity in proportion to the duration and intensity of the irritation. The objects, which are not always attained, are the removal by absorption or by extrusion of the noxious microorganisms, and the removal by absorption, without obvious loss of tissue, or the demarcation, with a view to separation and extrusion, of those parts which have been so altered that neither their absorption nor their recovery is possible. The idea that a destructive or an impaired action is a part of the process of inflammation must be carefully excluded. Briefly, inflammation, whether aseptic or septic, consists of the series of phenomena necessary for the removal, or for attempting the removal, of effete and irritating matter from a damaged area by the physiological processes of absorption, of extrusion, of demarcation and of revival, or by one or more of these.—*The Scottish Medical and Surgical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, November 10, 1906.

ANTHRACOSIS AND PULMONARY TUBERCULOSIS.

THE opinion that tuberculosis of the lungs is in the majority of cases the sequel of a primary infection, occurring—often many years previously—via the intestine and the mesenteric lymph nodes, has gained many notable adherents of late. Without going as far as Behring, who looks upon phthisis in the adult as the closing act of a drama beginning in the cradle, there is much that is rational in the conception of this mode of invasion of the tubercle bacillus, and experimental corroboration is not lacking. To mention only two of the most recent of the published observations relating to this subject, reference may be made to the work of Bartel and of Schlossmann. The former of these placed guinea pigs under appropriate conditions in the homes of consumptives, and found that those of the animals that became tuberculous in nearly every instance gave evidence of a primary intestinal infection. Schlossmann (see MEDICAL RECORD, August 4, 1906, p. 191) endeavored to demonstrate the route by which the germs probably make their way from the gastrointestinal tract to the lung by selecting animals so young that all likelihood of already existing tuberculous disease could be excluded, and under the proper precautions injecting tubercle bacilli into their stomachs. It was found that in some instances, after the lapse of only a few hours, tubercle bacilli had already penetrated to the lung. The experimenter expresses the conviction that the organisms passed through the intestinal wall and gained the mesenteric lymph nodes; from there they entered the thoracic duct, and thence through the venous blood stream found lodgment in the lung.

Ribbert, an authority whose opinion is worthy of the utmost respect, declines to accept this assumption. For him, now as before, the respiratory channel represents the chief portal of entry of the tubercle bacillus in pulmonary tuberculosis, though, of course, he is far from denying that the other mode of invasion does not frequently take place. In a recent communication (*Deutscher medizinische Wochenschrift*, October 4, 1906) he considers the bearing of anthracosis in the present problem and finds in the conditions thus produced a weighty argument in favor of his view. Contrary to those who assume that the deposit of coal dust is *per se* a deleterious process, capable of leading to damage to the pulmonary tissue, he believes that when harm results it is in consequence of a preexisting tuberculosis. In support of this he points out the scattered occurrence of the small—often only pinhead sized—calcareous anthracotic subpleural nodules that by a careful examination can very often be discovered in the lungs of those dying from nonpulmonary diseases. Although it is usually impossible, owing to their lack of all structure, to demonstrate by microscopic examination the tuberculous character of these nodules, the fact that whereas lesions due to the deposition of coal dust alone would be uniformly distributed, they are found fortuitously scattered in small numbers here and there, makes it evident that there must have been some localized inflammatory process to encourage the carbon particles to collect. Under these conditions the pigment grains would be prevented from being disposed of in the manner usual to healthy lung tissue and would become entangled in the connective tissue network. Of the various possible sources for these inflammatory foci, such as syphilis, abscesses, or infarcts, tuberculosis is the most probable. That it does play a rôle in this connection is shown by those calcareous nodules, black at the periphery and cheesy at the center, or possibly presenting giant cells and tuberculous granulation tissue, which are sometimes found.

These and a number of other considerations, the discussion of which, owing to limitation of space, cannot profitably be entered upon here, lead Ribbert to conclude that most anthracotic foci represent the late stages of healed tuberculous lesions. By a similar process of reasoning, the same conclusion is reached regarding the anthracotic bronchial glands. It would seem far-fetched indeed for any one to ascribe the subpleural nodules to bacilli that had entered the body through the alimentary tract, and Ribbert considers that their existence affords striking evidence of the aerogenous infection of the lung, and of the bronchial glands as well. Tubercle bacilli can, of course, readily penetrate the respiratory epithelium without leaving any traces, just as they can and do penetrate the intestinal mucosa.

Acceptance of this doctrine of the tuberculous nature of these very frequent anthracotic nodules has an interesting bearing on the statistics of latent tuberculosis. As our knowledge of the pathology of tuberculosis is broadened, the sweeping assertion that most of humanity is tuberculous, in the sense of harboring in one tissue or another demonstrable tuberculous lesions, seems more and more worthy of credence. Granted this wholesale infection of the human race, there follows the somewhat reassuring corollary that in view of the relatively small proportion of individuals who actually become diseased most of the population must be comparatively immune. In other words, the tubercle bacillus is a serious menace only to those who are in some way predisposed, for it is hardly credible that all the persons who present merely these insignificant latent lesions should have had the good fortune to encounter only nonvirulent bacilli. What the nature of this predisposition is, whether it is altogether innate or to some extent acquired, and whether, if it is acquired, any method will be discovered whereby it can be detected in time and in some way removed, are large questions to which the future may possibly have answers.

THE MEDICAL LICENSE LAW IN NEW YORK.

When one compares the present conditions of medical practice in the United States with those which existed only fifteen or twenty years ago it is evident that great progress has been made. At that time the regulation of practice was only in its infancy, and the attempts which were being made in some few States to protect the public from irregular practitioners of all sorts, and even from out-and-out quacks and ignorant charlatans, were regarded with suspicion and disapproval by many in and out of the profession. The pioneer efforts of the Illinois State Board of Health met with strong opposition, not only from the faculties of the small and inefficient colleges who feared a loss of students and of the fees they paid, but even from educated physicians with no college connection, who resented the slight restrictions then placed on medical practice as an interference with personal liberty. Gradually, however, the idea took root, and one State after the other passed laws regulating practice and establishing educational standards, to which all not already following their profession must conform before receiving permission to treat the sick. There is now practical unanimity regarding the necessity of medical license laws, and every State has such laws in force. The conditions have changed, and vastly for the better, but they are far from perfect. A lesser evil has been substituted for a greater one, for it is unquestionably an evil that the educated physician practising his profession lawfully and skilfully in one State should become a criminal and a quack in the eye of the law if he attempted to continue his activity, after removing to another State, without submitting to a second examination under a licensing board. A federal license law has been suggested as the remedy for this evil, but the form of government under which we live renders this impossible. Each State is sovereign in this respect, and the federal government cannot coerce it. The only remedy lies in universal reciprocity, but this is manifestly impossible as long as the requirements in each State are not uniform. At present no two State medical license laws are the same; some are rigid and some are lax, and if reciprocity were now general, the poorly prepared candidates, in whatever place they intended to practise, would naturally come up for examination in the States where this was the most easy, and the general standard would fall to the level of the lowest. Until the laws in all the States are made uniform, or practically so, universal reciprocity in medical licensure must remain impossible.

The Educational Council of the American Medical Association has been very active of late in the endeavor to raise the standard of preliminary and professional education in the various States, and the work it has done is commendable, but we question whether it will ever succeed in bringing about uniformity in the medical laws. The solution of the problem rests with the practitioners in each State. If they will interest themselves in the subject, and will use their influence to obtain amendments to the present laws, the time will come when all the States will have requirements which are practically equal, and then universal reciprocity will naturally follow.

New York State was among the first to enact a medical license law, good in its way, but not perfect. It is the Empire State of the Union, with the largest population and the greatest number of medical practitioners, and it ought to establish a standard to which the medical laws of the other States would conform. But before it can set itself up as an example for other States to follow, it must amend its requirements in several important respects. The *Post-Graduate* for October contains a thoughtful article by Dr. Frank Van Fleet on "Needed Reforms in the Medical Laws of the State of New York," which is worthy of study by legislators in other States as well. The writer, whose familiarity with medical legislation in this State qualifies him to speak with authority, pronounces our present law defective on four counts: "(1) It is cumbersome; (2) It discriminates in favor of certain classes; (3) It does not accomplish the purpose for which it was enacted; (4) It is unjust in its method of enforcement." The first objection calls for no comment, for it is a question of form rather than of matter. The second count relates to the fact that there are three distinct examining boards, composed of regular, homeopathic, and eclectic physicians, respectively. This provision of the law is bad, in that it does not safeguard the people against ignorance in the one branch which is the end and aim of medical study—the cure of disease. A man who has passed the examination before any one of these boards is a legally qualified physician and entitled to treat his patients in any way he pleases. It is conceivable that a student with a knowledge of only the homeopathic or eclectic materia medica may be qualified by his own board, and then decide to throw over sectarian practice; but he is really unqualified so far as regards therapeutics, and has practically been admitted to practice without examination in the most essential branch. Again, if the State recognizes two "schools" as distinct from regular practice, there is no reason why it should not recognize a dozen others. So long as this distinction exists the osteopaths have a strong argument for their demand for a separate board to examine their candidates and grant them a license to practise their own or any other therapeutic eccentricity. If they should gain their point it is difficult to see how recognition could then be refused to the naturopaths, the vitapaths, and even Mother Eddy's nihilists.

The law is also defective in that it does not define clearly the practice of medicine. Everyone knows instinctively in what this consists, yet a judge in this city not long since ruled that the practice of medicine consisted in the giving of drugs. One might treat a mild case of typhoid fever without giving a single dose of any drug listed in the Pharmacopœia, yet no sane man outside of the legal profession would contend that he was not practising medicine in caring for the patient. The law is also unjust, in that it throws the burden of enforcement upon the county medical societies—homeopathic, eclectic, or regular—instead of using the machinery already provided for the conviction and punishment of other malefactors.

So far as the requirements, preliminary and professional (materia medica and therapeutics ex-

cepted), are concerned, the New York law is all that could be desired, and no other State can object to reciprocity on this ground; but in some respects it should be amended. There should be but one examining board to examine all candidates, and as long as the State recognizes the two schools in addition to regular medicine, representatives of each of these schools should be in the board; the law should clearly define in what consists the practice of medicine, or, as Dr. Van Fleet prefers, "the practice of the healing art;" and, finally, it should make provision for the punishment of offenders against the law, and not leave this to the initiative of individuals or societies. The State of New York should have a medical practice law as perfect as any law can be —one which could be taken as a model in the framing of the laws of other States, and it would so be taken if it were really model in all its provisions. Then what now seems to be the Utopian dream of universal reciprocity would become a fact, and a physician licensed after examination to practise in any one State would be entitled, after complying with the necessary formalities, to follow his profession anywhere in the United States or its dependencies. It rests, then, with the physicians of the individual States to secure the enactment of perfectly satisfactory and practically uniform medical practice law, and thereby bring about universal reciprocity in medical licensure.

Plans of the Sea View Hospital.

The plans of the proposed hospital for tuberculosis on Staten Island, to be called the Sea View Hospital, were recently submitted for approval to the State Board of Charities. The plans call for the erection of eight buildings, each four stories in height, for the wards, a dining hall and kitchen building, an amusement hall, and administration buildings, at a total cost of $2,000,000. The approval of the plans was strongly opposed by Dr. Stephen Smith, who objected not only to the cost but also to the plan of construction. The present approved treatment of tuberculosis, he said, is by means of fresh pure air and sunshine—practically outdoor life. This result can best be secured in simple one-story structures, varying in design from the tent, the shack, the lean-to, to the pavilion with numerous windows extending from floor to ceiling and wide verandas. He objected therefore to the plan before the Board which provided for four-story buildings each accommodating one hundred patients distributed in four wards one above the other. These buildings are to be of reinforced concrete and therefore permanent, whereas hospital buildings for infectious diseases should be susceptible of ready renewal. Since he believed the food of the patients should be made up chiefly of milk and eggs with fruits and cereals, Dr. Smith took exception to the expenditure of over $340,000 for a dining hall and kitchen building. He thought also that the buildings designed for the accommodation of nurses, attendants, and help, and the "Amusement Hall" were on much too large a scale and too expensive. Indeed, the proposed cost of the entire hospital was, he held, excessive. He said that it is estimated by competent authority that a hospital or sanatorium for the exclusive treatment of tuberculosis could be constructed in all its appointments for a sum not to exceed $400 per patient, but the plans for the Sea View Hospital called for an expenditure of $2,638 per patient. If the buildings were economically constructed, on strictly scientific, medical, and sanitary principles, the money apportioned would provide for 5,276 instead of 800 tuberculous poor of New York. Dr. Smith's main objections would seem to be well taken. There is a manifest tendency at this time to a liberality bordering on extravagance in hospital construction, and it is legitimate to inquire whether such expenditure is altogether justifiable.

Lymphocytosis of the Cerebrospinal Fluid.

The lymphocytosis which is often observed in tabes may be accounted for by the anatomical localization of the disease, for tabes is believed to begin as a diffuse meningitis which extends to the posterior roots and columns. The irritation of the meninges is sufficient to account for the increase in the number of lymphocytes in the cerebrospinal fluid. A similar condition has also been noted during the second stage of syphilis, in which the nocturnal headaches also point to meningeal irritation. Involvement of the nervous system during tertiary syphilis is quite constantly accompanied by a cerebrospinal lymphocytosis, whereas it is present in only about one-half the cases in which a gumma is localized in some other portion of the body. In syphilitic hemiplegia we also meet with a lymphocytosis of the cerebrospinal fluid, while this is not present when the condition is due to cerebral softening or hemorrhage, so that in this instance it may be accepted as a differential diagnostic sign. It is not possible, however, to clear up the diagnosis in every case by merely finding a lymphocytosis of the cerebrospinal fluid, as pointed out recently by Widal. In the case in question, that of a woman of seventy-one, the clinical picture was that of a subacute myelitis, and a closer examination showed a condition similar to a Brown-Séquard paralysis. Fluid obtained by lumbar puncture disclosed evidences of a marked lymphocytosis, although this might also have been due to a herpes zoster of long standing or to an unrecognized syphilitic infection. The lymphocytosis afforded no clue, therefore, to the true condition, adding thus one more to the numerous instances showing that a laboratory finding can be considered of value only when it is weighed with the other features of the case.

The Storage of Iron in the Organism.

There exists considerable difference of opinion regarding the fate in the organism of iron administered for therapeutic purposes, and many have seriously doubted whether it is really taken up by the system under these circumstances. Some light may be thrown on this question by observations recently made by Grober (*Medizinische Klinik*, No. 30, 1906) in patients suffering from chronic ulcer of the stomach. The subjects of this condition, usually women, are almost always anemic or chlorotic, and more or less emaciated. To a number of these Grober administered a diet consisting of milk and other articles known to be free from iron, or containing only a small proportion. The patients were kept in bed absolutely quiet. Within a few days there was a decided improvement in the general condition, and at the end of a week a well-marked increase in the hemoglobin content of the blood could be demonstrated. In other cases in which the hemoglobin had been reduced by gastric hemorrhages and the fear of a recurrence prohibited for days the taking of anything more than a few swallows of

cold milk, the same increase was observed. During a period of starvation the hemoglobin is not therefore reduced, as might be expected, but, on the contrary, becomes increased. Iron compounds are being constantly disintegrated in the human organism, and the iron is excreted chiefly by the intestine. Notwithstanding this it seems that the hemoglobin content may remain unchanged, or even be subject to an increase. There must be stored away in the organism somewhere a supply of iron in reserve, regarding the locality and form of which we are still in ignorance. Further observations on this subject will meet with deserved attention.

Plastic Operation for Hydronephrosis.

The operative treatment of hydronephrosis has developed along various lines depending on the individual indications, but in the main there are two leading types, the conservative and the radical. The former has been largely developed by Trendelenburg, who endeavored by plastic methods to change the dilated pelvis of the kidney in such a way that new drainage facilities would be provided and urinary retention avoided. This is accomplished by freeing the ureter at its emergence from the renal pelvis and suturing it to the deepest portion of the distended sac. Free drainage of the pelvis is thus accomplished in a manner approximating the normal. An extended trial of this method has been made by Läwen (*Zeitschrift für Chirurgie*, Vol. 79) in a series of thirteen cases of hydronephrosis, in which nine patients were completely relieved. In consideration of the unfavorable conditions which are present in many of these patients a larger percentage of cures can hardly be hoped for, and one must regard the result here attained as excellent.

News of the Week.

An Epidemic of Typhoid Fever at Wesleyan.—Several cases of typhoid fever have developed at Wesleyan University, Middletown, Conn. An investigation by Prof. Conn of the University has shown that the cases were due to contaminated oysters eaten by students at banquets of the various fraternities on October 12. It was at Wesleyan University that a similar epidemic, a number of years ago, found to be due to the eating of infected oysters, called attention to this mode of transmission of the disease.

Hospital Conference.—At a meeting of the Hospital Conference of the City of New York, held at the Academy of Medicine on October 30, it was decided to study systematically the following subjects relating to hospital management: Hospital expenditure, uniform accounting, State inspection and municipal aid, the distribution and classification of hospitals and hospital beds in relation to the needs of the community, ambulance service, dispensaries, medical organization and medical education, paying patients, cooperation of hospitals with each other and with other relief agencies, the treatment of patients in their own homes. A resolution was adopted providing for the appointment of a Committee of Investigation to consist of ten members. This committee will be subdivided into committees of one, to each of whom will be assigned one or more of the preceding subjects for investigation and report. It is provided that the Committee of Investigation shall have the right to offer reports and to make recommendations to the Conference as a body, but each member of the committee shall have the right to present to the Conference at any regular meeting a report on the subject especially assigned to him, and the reading of such reports shall constitute part of the regular order of business of the Conference. The substance of any report made to the Conference by an individual member of the Committee of Investigation, may be published by him unofficially as a personal document; but no report shall be published as an official document of the Conference unless it shall have been adopted by the Conference by vote and unless, following its adoption, its publication is ordered by the Conference on the recommendation of the Executive Committee.

Manhattan Eye, Ear, and Throat Hospital.—The new building of this institution was dedicated on October 30, by a service held in the Agnew Memorial Library in the presence of a large number of medical and lay guests. The new building is seven stories high. It has a frontage of seventy-five feet and a depth of one hundred feet, and stands on a plot of ground covering four lots on Sixty-fourth street and three lots on Sixty-third street. The ground, building, and equipments cost about $700,000. The hospital is of brick, with white marble trimmings, and is fireproof. The main wards are on the lower floors, and in the rear are sun balconies for convalescents. On the top floor are three operating rooms and laboratories for research work. On the fourth floor there are twenty-seven private rooms, with a special entrance and elevator. The Agnew Memorial Library, on the third floor, is in memory of Dr. Cornelius Ray Agnew, the founder of the institution. In the hospital will be 150 beds, or three times the number in the old building at Forty-first street and Park avenue.

The City's Tuberculosis Hospital.—The sum of $225,000 has been appropriated for the erection of buildings on the site selected by the municipal authorities for the proposed tuberculosis hospital at Otisville, a settlement in Orange County, seventy-seven miles from New York City. The land has an altitude of about 1,400 feet, and it is proposed to provide for the accommodation of about two hundred patients, who will be either persons in the incipient stages of the disease or convalescents from the hospitals. It is expected that the construction and equipment of shacks for patients will cost $80,000, and the dining room and kitchens $20,000 more. A barn for forty cows will cost $18,000. The power plant is to be built for $30,000, and the rest of the appropriation will go for dormitories, employees, roadways, paths, and general improvements.

Jewish Hospital for Deformities and Joint Diseases.—This institution was formally opened on November 4, and a reception was held by the officers and directors. The hospital is installed in a remodeled three-story building on Mount Morris Park at 1917 Madison avenue. In the basement are the offices and reception rooms for patients. The second floor is devoted to private examination rooms and *x*-ray room. On the third floor are the various wards. Most of the fourth floor is devoted to the operating room. The hospital is the outgrowth of a dispensary opened two years ago by Dr. Henry W. Frauenthal at Fiftieth street and Lexington avenue, and is nonsectarian.

Report of Chicago Pasteur Institute.—A summary of the results of preventive inoculation against hydrophobia has been published by this institute since its inauguration in 1890. A total of 2,775 patients have received the antirabic treatment; of these, 2,474 were bitten by dogs, 100 by horses, 84

by cats, 29 by cows, 23 by skunks, 9 by calves, 9 by wolves, 5 by pigs, 4 by coyotes, 4 by mules, 2 by burros, and one each by a rat and a sheep. Hydrophobic human beings infected 31 patients. Of the patients, 1,406 had received severe and multiple bites on the hands and wrists, 584 on the leg and thigh, 388 on the face and head, 359 on the arms, and 42 on the trunk. Only seven deaths were reported, giving a mortality rate of 0.25 per cent. Seven individuals gave up treatment, two of whom died subsequently from hydrophobia.

Chicago Home for Nurses Finished.—The new $30,000 Harris home for nurses at Wesley Hospital was recently accepted formally by the Trustees of the Hospital at their annual meeting. The home is the gift of N. W. Harris.

Army Nurses in England.—The British Secretary of War has recently had to decide the question raised in the House of Commons as to whether the nurses at Netley Military Hospital may go to dances. The Secretary came to the conclusion that occasional attendance at operas, theaters and concerts is not incompatible with the due performance of the duties of the nurses, but the late hours involved in balls and dances incapacitated them from giving the proper attention to the patients.

Statement of San Francisco Medical Relief Committee.—The Medical Relief Committee representing the New York Academy of Medicine, and the Medical Societies of the Counties of New York and Richmond announces that the total sum transmitted to the Medical Relief Committee at San Francisco amounted to $7,701.10.

To Restrict the Opium Trade.—At the jubilee convention of the National Temperance League, held in London last week, the Rev. Wilbur F. Crafts, a well-known reformer, introduced a resolution to petition all civilized countries to extend the scope of the Brussels convention of 1906, with the view to suppressing the trade in opium and intoxicants among uncivilized peoples. The resolution was adopted unanimously. The speaker stated that the only country in which the consumption of liquor was not increasing was the Congo Free State, where there was an international prohibition by seventeen countries.

Yellow Fever on a Transport.—The departure from Havana of the transport *Sumner* was delayed on November 3, owing to the discovery that one of the infantry officers on board was suffering from yellow fever. The patient, who had only recently arrived in Havana, was taken to Las Animas Hospital.

Radium in the Customs House.—The official status of radium as an import is proving a difficult question for the board of appraisers to determine. The Dingley tariff law makes no specific provision for radium, and importers have objected to the ruling that radium as a chemical salt is subject to a duty of 25 per cent. Application has been made to the board to review this decision, and the matter is being investigated by the General Appraiser.

Sleeping Sickness Cured.—According to reports said to have been received at Marseilles from French physicians in the tropics the majority of one hundred and fifty patients suffering from sleeping sickness have recovered under the use of thymol.

Death Penalty Abolished in France.—At a cabinet meeting held in Paris on October 30 a measure was approved providing for the abolition of the death penalty. This means that the Chamber of Deputies at its coming session will probably enact a law to that effect.

Tuberculosis in the Navy.—In his annual report submitted to Secretary of the Navy Bonaparte, November 2, Surgeon-General P. M. Rixey of the navy calls attention to the fact that tuberculosis is increasing in the navy and Marine Corps. The report states that if gunshot wounds, drowning, burns, and local injuries are eliminated, tuberculosis as a cause of death in those branches of the military service would stand second in 1900, fourth in 1901 and first for the past three years. In 1895 the ratio of cases per one thousand was 3.2, in 1905 it was 6.1.

Typhoid Fever in Jersey City.—Owing to the occurrence of 53 cases of typhoid fever in Jersey City during the month of October as against four cases in September, the Board of Health is taking active measures to impress on people the necessity of using only boiled water for drinking. It is stated that the city's water supply is being polluted in the Rockaway River valley at Boonton and Dover. The action of the Health Board is being opposed by some others of the city officials on the ground that the warning to the people is actuated only by political motives.

New Medical Directory of the State Society.—The eighth volume of the Medical Directory of New York, New Jersey, and Connecticut has been published and is being distributed. It shows that there are registered in Greater New York 6,034 physicians, and in New York State 11,976. Connecticut has 1,279 and New Jersey 2,276. The total number of names is 15,531.

Obesity Pills Barred.—The manufacturers of a widely advertised remedy alleged to cure obesity have been stopped from using the mails in consequence of a fraud order issued by authority of Postmaster-General Cortelyou. The pills were sold at $2 a box with the claim that they would reduce weight at the rate of eight ounces a day.

Newspaper Prodigies.—From Russell County, Ky., comes the report that a man of sixty-three years, resident in Rowena, has remained in a state of catalepsy twelve years. During this time he has received liquid nourishment twice a day, and his physical condition is said to be excellent. It is also reported that at a laporotomy recently performed on an insane man an iron bolt five inches long was removed from the intestine.

International Medical Association of Mexico.—The second annual meeting of this organization will be held in the *Herald* Club Rooms, in the city of Mexico, November 14 to 17, 1906. Excepting the papers by the Spanish members, the proceedings will be in English. The president of the society is Dr. R. D. Robinson of Torreón, Coah., and the secretary is Dr. W. R. Jamison of the same city.

Thurber (Mass.) Medical Association.—At the fifty-third annual meeting of this society, which was held in Milford on October 25, officers were elected as follows: *President,* Dr. O. C. B. Nason of Medway; *Vice-President,* Dr. C. H. Randall of Franklin; *Secretary,* Dr. A. J. Gallison of Franklin; *Treasurer,* Dr. C. B. Hussey of Franklin.

Sixth District Illinois State Medical Society.—At the meeting of this body held in Jacksonville on October 26 the election of officers resulted as follows: *President,* Dr. T. J. Pitner of Jacksonville; *First Vice-President,* Dr. Waldo Fisher of Alton; *Second Vice-President,* Dr. W. H. Hand of Whitehall; *Secretary and Treasurer,* Dr. W. P. Duncan of Jacksonville.

Chicago Urological Society.—At the annual

meeting of this society, the following officers were elected for the ensuing year: *President,* Dr. L. E. Schmidt; *Vice-President,* Dr. J. Allen Patton; *Secretary,* Dr. B. C. Corbus; *Councilor,* Dr. Wm. T. Belfield; *Alternate,* Dr. Henry G. Anthony.

Erie Railroad Surgeons.—The fifteenth annual meeting of the Association of Erie Railroad Surgeons was held at Chicago October 9 and 10, 1906. The next meeting will be in New York, October, 1907. The officers for the ensuing year are: *President,* Dr. D. A. Currie, Englewood, N. J.; *Vice-President,* Dr. T. D. Bain, Kenton, Ohio; *Secretary and Treasurer,* Dr. J. A. Allis, Upper Montclair, N. J.; *Executive Committee,* Dr. C. E. Sawyer, Marion, Ohio, Dr. S. Heilman, Sharon, Pa., and Dr. A. W. Booth, Elmira, N. Y.

Obituary Notes.—Dr. Thomas Stevenson of this city died suddenly on October 27 at the age of forty-one years. He was graduated from the Bellevue Hospital Medical College in the class of 1888, and was a brother of Dr. George Stevenson of this city.

Dr. Samuel Tinlock, one of the few Chinese physicians practising in this country, died of tuberculosis on November 2 at the age of seventy-two years. He had been a resident in New York's Chinatown for the last forty years. He was converted to the Roman Catholic faith many years ago and married a white woman, who survives him.

Dr. Charles Jenkins Finn of Hempstead, L. I., died on November 2 of apoplexy. Dr. Finn was born in Brooklyn in 1856 and began practice in Hempstead in 1876. He was a member of the Board of Education of Hempstead and was one of the surgeons of the Long Island Railroad. He was the family physician of many of the summer residents who have estates in the neighborhood of Hempstead.

Dr. Robert T. Davis of Fall River, Mass., died on October 30 at the age of eighty-three years. He was born at Amesbury, Mass., and received his medical degree from the Harvard Medical School. He was a former Mayor of the city of Fall River and served three terms as Republican representative in Congress. He had been a resident of Fall River for fifty-six years, and was one of its wealthiest and most prominent citizens.

Dr. J. W. Howard of Missoula, Mont., died at Great Falls on October 20 at the age of fifty-three years. He commenced the practice of medicine in Oregon in 1878, and in 1887 went to Montana and settled in Dillon. He also had practised in Butte, Bozeman, and Hamilton before going to Missoula.

Dr. J. W. Cooper of Bellaire, W. Va., a well-known physician of the Ohio Valley, died in Wheeling on October 29, after an illness of several years. He was a son of Dr. Cooper of Wellsburg, W. Va., but had practised for some years in Bellaire.

Dr. Andrew Jackson Runnells of Walpole, Mass., died on October 22 at the age of eighty-three years. He had been a practitioner for more than fifty years, but retired from active work ten years ago.

Dr. Ruel W. Dwight Rice, a retired U. S. Army surgeon, who served through the Civil War, died on October 22 at his home in Alameda, Cal. He was born in New York State eighty-six years ago.

Dr. Archibald Frazer of Ypsilanti, Mich., died on October 27 at the age of sixty-two years. He was graduated in 1870 from the New York Homeopathic Medical College and in 1879 settled in Ypsilanti.

Dr. Luis F. Urcelay of Merida, Yucatan, died suddenly of apoplexy on November 2 while bound for this country on the steamer *La Lorraine.* Dr. Urcelay was the head of the recently completed O'Haron Hospital in Merida, and had gone to Europe in order to recuperate after his arduous work in the hospital.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PLAGUE COMMISSION—LATE RICKETS—UTERINE TUMOR—TUBERCULOSIS OF CERVIX UTERI—STERCORACEOUS OF THE APPENDIX VERMIFORMIS—ACLAND HOME—GUILD OF ST. LUKE—QUACKS COMMITTED—OBITUARY

London, October 19, 1906.

The inquiry instituted at the instance of the Lister Institute by the Government of India into the spread of plague reinforces the theory that the disease is chiefly transmitted by the flea of the rat. The report of the Commission has not yet appeared, but some of its operations and conclusions have been published by the authority of the advisory committee and are recorded by the *Journal of Hygiene.*

The association of rats with epidemics of plague has been noticed for generations, but the manner of communication was not established. Kitasato and Yersin showed that the bacillus was the same in rats as in men, but it was not until some seven or eight years ago that the flea was suspected to be the carrying agent. The Indian Commission has shown that plague can be so transmitted. Simond eight years ago satisfied himself that the flea could convey plague from one rat to another, but it was thought the rat flea did not infect other animals or men—a view now known to be untenable. The experiments of the Commission show that a common Indian rat infected with plague does not transmit the disease if no fleas are present. On the other hand, if fleas are present, plague may spread from an infected rat to a healthy one confined in a separate cage so as to prevent these animals coming into contact. Plague may be communicated to guinea pigs, and these may be let run among healthy animals, provided no fleas are present. An infected animal may suckle its young without giving them plague, provided no flea is present; but let fleas have access and the plague spreads from one to another, according to the number of fleas present. Other experiments and observations seem to prove that rat fleas in a house which has been disinfected after plague cases will give the disease to guinea pigs, the fleas being caught on these animals and placed on others which succumbed. The bacillus was found in the stomachs of the fleas. If houses in which plague had occurred were found to be freed from fleas, the bacillus disappeared from them sooner than had been previously supposed; but so long as they remained infection would continue.

At the Clinical Society the president, Mr. Clutton, delivered his address. Subject, Adolescent or Late Rickets. His first case he met with three years ago; a man at twenty-one, who at twelve had had to wear supports for genu valgum, and on whom osteotomy was done at sixteen for both knees. At nineteen curvature resembling genu recurvatum began. Patient shown, and skiagrams showed changes in the bone were of long duration, and apparently began at the epiphyseal lines. In the shafts adjoining the epiphyses there was much less cortex than normal and a large translucent medulla, and here the curvature had apparently begun. Diagnosis was established by the active state of rickets in the wrists, as seen in both radius and ulna by *x*-rays. Almost all the long bones showed changes at the ends of the diaphyses adjoining the epiphyses. Two other cases at twelve and fourteen were shown by skiagrams showing the disease in a recent state, the contrast with the older cases being most interesting. Two post-mortem specimens were also exhibited, one from the College of Surgeons and one from the Children's Hospital. A number of skiagrams taken by Dr. Greg at St. Thomas's Hospital were also shown.

Mr. E. Muirhead Little described, with the specimen from the College of Surgeons, a case occurring in a girl of seventeen in whom infantilism was well marked and the changes in the bones were extremely typical of rickets. At the operation the bone was quite soft.

Mr. Lucas, referring to a paper in which he had tried to show a connection between late rickets and intermittent albuminuria, said the emotional state of puberty favored the occurrence of both.

Dr. P. Weber recalled that Wright had shown that calcium salts would cure most cases of cyclic albuminuria, but had little or no effect on rickets.

Mr. R. C. Elmslie showed two cases and remarked on the difficulty of tracing the origin, the history obtainable being incomplete or untrustworthy. In many cases in which he had by the *x*-rays found rickets the condition was quite unknown to the mother., The signs might all disappear by the age of eight, except the puny development and head changes, particularly a curious high forehead. These features he always found in late rickets, and they suggested an early origin.

At the Obstetrical Society Drs. Eden and Provis related a case of intraligamentous fibrocystic uterine tumor weighing about thirty pounds removed by enucleation and incomplete hysterectomy. The patient died the next day, but post mortem could not be obtained. It was thought embolism was the cause of death, as there were complications suggesting such an occurrence.

Mr. Eric Young then read an account of a case of primary tuberculosis of the cervix uteri in a thin, nervous woman of twenty-six, married, healthy up to six months before seen. Thick, yellow discharge, a constant pain in back for five weeks, no bleeding, no glandular enlargement; cervix indurated and swollen, uneven, ulcerated in places, nodular, not friable; uterus freely movable; lungs healthy; no sign of tubercle elsewhere; none in family. Hysterectomy was done. Six months later no recurrence. Dr. Routh said the case was important in reference to the relative frequency of tubercle of the cervix and Fallopian tube. Dr. Lewers had had such a case and the patient remained well for several years after the operation. Dr. Galabin had had a case in which the body of the uterus had become involved so that hysterectomy was the only resource. Dr. Andrews had seen a similar case turn out to be syphilitic.

At the Medical Society of London the vermiform appendix was again under discussion—this time as the subject of actinomycosis, or, as some prefer to call it, streptothrichosis, as other forms of streptothrix than the ray fungus may be concerned in the disease. Mr. T. H. Kellock read the paper and gave some account of seven cases which had occurred at the Middlesex Hospital within the last three years. He described two types of the disease: (1) Simple streptothrix infection in or about the appendix; (2) a graver infection complicated by the presence of pyogenic organisms. In quiet cases slight, long-continued pain and indurated tissue were the clinical features. In suppurating cases early signs were followed by burrowing abscesses. When diagnosis was clear, operation was advised. There was some discussion of the paper and one of the speakers held that a cecal origin could not be excluded in most cases, if any, while as to treatment, operation alone was not sufficient, but iodide of potassium was also necessary to effect a cure.

Professor Osler opened the new wing of the Acland Home on Saturday. He read a letter sent by direction of the Queen, congratulating Miss Acland, to whose exertion much is due, on the success of the institution which bears the name of her great and good father. Dr. Osler remarked that with 3,000 undergraduates it was important to have a home to which they could apply in serious illness. It was established as a memorial of Mrs. Acland and the late honored professor.

The Guild of St. Luke had its annual service at St. Paul's on Wednesday, when above two hundred doctors in robes attended. The master and wardens of the Apothecaries' Company, wearing their blue gowns, trimmed with sable, formed a little procession and were conducted to seats in the choir. Then came the large choir, followed by the robed doctors, walking two and two. Dr. A. Caley read the first lesson (Eccles. xxxviii.) and Sir Dyce Duckworth the second (Luke xiii.). Canon Newbold, warden of the guild, preached from the Third Epistle of St. John, second verse, and dwelt on the work of doctors and clergy in the cause of health, bodily and spiritual, appealing to medical men to join with the clergy in work which both desired to promote.

Two quacks were committed for trial on Wednesday, charged with obtaining money by fraud. For years they have driven a thriving trade by advertising that the Rev. J. Hope would tell incurable patients of a remedy. On application powders were recommended; price, 18/6. Analyzed, they were found to consist of a mixture of sodium carbonate and potassium bromide, colored with bark, and valued at 2d. From January to September they netted £3,300 from ignorant sufferers, some of whom testified that they trusted the reverend gentleman and had no idea that he did not exist.

Dr. E. R. H. Pollard, M.R.C.P.I., 1887, Inspector-General of Hospitals and Fleets and First Inspector-General of the Royal Naval Hospital, Chatham, died in that institution on the 9th inst., aged fifty-one.

Lieut.-Col. C. S. Wills, C.B., late of the R.A.M.C., died on the 12th, after a long illness, aged seventy-two. He entered the army in 1860 and saw much service. In the Zulu War of 1879 he was P.M.O. and Sanitary Officer, Director of Hospitals, etc., was mentioned in despatches, awarded the medal, and retired as Lieut.-Col. and C.B. in 1889.

Surgeon-Major Walter Leach, R.A.M.C. (retired), died on the 13th, aged seventy-eight. He entered the Army Medical Department in 1854 and retired in 1875. He went through the Central Indian campaign, was present at several battles, for one of which he was awarded the medal.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

SALT-FREE TREATMENT OF EPILEPSY—THE BIRTH RATE IN SWEDEN—A MODIFIED RIVA-ROCCI APPARATUS—PROFESSOR HAMMARSTEN'S JUBILEE—COMPETITION FOR THE CHAIR OF SURGERY.

COPENHAGEN, October 16, 1906.

It will be remembered that Toulouse and Richet in 1900 recommended a new treatment of epilepsy, consisting in the withdrawal of sodium chloride from the food. The explanation of the good results was said to be found in the circumstance that the bromides, given to the patient, would show a greater efficacy. The treatment has been tried in many places, but the last word has not yet been said regarding its value. In Denmark the treatment has been tried by Dr. A. Sell, physician in charge of an asylum for epileptics, with nearly two hundred inmates. On the whole, he approves of the treatment, but a recently published research by Dr. Hermann Lundborg, physician of the Upsala Asylum (Sweden), would seem to show that not all cases are favorably influenced by it. Lundborg states that the treatment very often causes a remarkable decrease in the number of attacks, but, on the other hand, not seldom also a deterioration of the psyche. It would seem that the treatment ought only to be applied in asylums, infirmaries, and other places, where the patient is under constant supervision. It is indicated in cases with relatively frequent attacks without pronounced psychical accidents; in cases with transitory psychoses, when these appear in connection with attacks, the intervals being as free as possible; finally, in torpid forms of epilepsy without too pronounced stupor. The treatment is contraindicated in cases with grave complications in lungs, heart, vessels, or kidneys; in cases complicated by hysteria or epileptiform hysterical attacks; in cases of a pronounced erethistic type, and, finally, in cases in which stupor is more or less constant.

Another distinguished Swede, Prof. Pontius Fahlbeck, has published a highly interesting investigation into the birth rate of our time with special reference to Sweden. The many important statements made by the writer cannot but make a deep impression on all those who feel alarmed at the decrease in fertility of the human race in Europe. I shall here reproduce some of Professor Fahlbeck's results. In a table, giving the number of living born per 1,000 of the population, we see that France has gone down from 25.5 in the lustrum 1871-1875 to 21.9 in 1896-1900; Sweden during the same periods from 30.7 to 26.9, Denmark from 30.8 to 29.9, while Norway has remained stationary at 30.3, and Russia, blessed with the greatest relative number of births, shows a decrease from 50.2 to 48.3. On an average the tendency is toward a constant diminution of the birth rate in all European countries. Setting aside the comparatively unimportant amount of illegitimate births (an average for all Europe 6.18 per 100 of all living born), the question arises whether the diminishing birth rate is due to a decrease in the number of marriages or to a decreasing fertility in matrimony. In this connection it is interesting to note that the relative number of marriages is nearly constant in all European countries and equal to 7 or 8 per 1,000. Only Sweden and to a lesser degree Norway form exceptions to this rule. Until 1825 the marriage rate in Sweden was the same as that of the other European countries; but after 1825 the number began to decrease, and now it amounts only to the exceptionally low value of between 5 and 6 per 1.000. As regards Sweden and Norway, the explanation of the diminishing birth rate may consequently be found in the decreasing number of marriages, while it is evident *a priori* that a decreasing fertility must be the causing factor in the remaining European countries. But even the two Scandinavian peoples show a lessening fertility. The yearly number of births per 1,000 married women in the ages from fifteen to forty-five years amounted for Sweden during the period 1871-1880 to 300.9 against 276.1 during 1891-1900; for Norway the numbers were 322.5 and 311.1, for Denmark, 286.4 and 269.8, while France presents the appallingly low figures of 201.4 and 174.4.

The decrease in the birth rate, thus shown generally to exist, is neither caused by physiological alterations nor by an increasing poverty among the masses. On the contrary the wealth of the nations every day becomes greater; for the best authorities compute the annual sum of savings in France alone to be between two and three millions. According to Professor Fahlbeck it is the two-children system adhered to by an ever-increasing number of couples that causes the diminishing fertility. This system, if generally accepted, will, under the most favorable circumstances, yield a birth rate of at the utmost 13.2 per 1,000. Now the death rate is between 15 and 16 per 1,000 and cannot very well be expected to become lower than 15 per 1,000. The system will consequently result in what may be called a suicide of the nation, as in the Hellas of antiquity, where Polybius noted its deleterious effects more than two thousand years ago. To one drawback more connected with the said system the author draws attention. It would appear that if the two-children system had been generally adhered to in former days the peoples would have missed many of their great men, many of whom have been one of the latter links in a long chain of brothers and sisters.

Dr. H. T. Bing, whose investigations into the methods for estimation of the blood pressure I mentioned in my last letter, has now constructed a modification of the Riva-Rocci apparatus, aiming at the elimination of the errors due to the circumstance that the ordinary apparatuses indicate the lateral pressure instead of the end pressure in the artery. He seems to have succeeded, as a series of experiments show, that the values of the arterial tension indicated by Bing's apparatus are higher than those given by an apparatus of the original Riva-Rocci type, and that they are far less influenced by local peripheric or thermic irritants.

The famous Swedish Professor of Physiological Chemistry, Professor Hammarsten, has just celebrated his sixty-fifth anniversary. A stately volume containing researches by his present and former pupils has been published in his honor.

Dr. Schaldemose will be appointed successor to Professor Wanscher, who died six months ago. The competition has been very close, not less than eight of our most prominent younger surgeons having entered it. Each competitor had to publish a work of no small size on a surgical topic of his own choosing and to deliver a clinical lecture with three hours' preparation. Three of the competitors, Drs. P. N. Hansen, Lendorf, and Schaldemose, were then admitted to the final trials, consisting in a lecture on a surgical theme, the same for all of them, and communicated to them twenty-four hours in advance. It is generally reported that the judges found it very difficult to decide which of the three mentioned surgeons was most qualified to succeed to the disputed chair.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 25, 1906.

External Eye Inflammations of Doubtful Origin.—Two cases are recorded by H. G. Langworthy. In the first case a young man of twenty-six suffered from a bilateral orbital cellulitis and exophthalmos simulating cavernous sinus thrombosis and double frontal involvement. The infecting organism was probably the pneumococcus. In the second case a young man of eighteen was the subject of acute bilateral edema of the eyelids of unknown origin. The diagnosis seemed to lie between angioneurotic edema and inflammation of both frontal sinuses. Both patients recovered. The author appends a bibliography of similar cases.

The Routine Treatment of Syphilis with Intramuscular Injections of Mercury Salicylate.—In this paper W. H. Palmer covers familiar ground. Nothing especially new is brought forward. He discusses the question under the headings of advantages of the salicylate over other mercurial salts, the advantages of this method over other methods, the disadvantages of the salicylate, changes produced in the tissues at the site of injection, the preferable injection site, the suspension fluid, the question of sterilization of the solution before injection (which he does not consider absolutely necessary), syringe and needles and their proper care, technique, dosage, and duration of treatment. He refers to an interesting case reported by Kalisch who met with a gumma which occurred at the point where an injection had been given five years previously. The gumma was incised and microscopical examination showed a minute amount of unabsorbed mercury which had probably acted as a local irritant, and in this way had determined the development of a gummatous lesion in this situation.

New York Medical Journal, October 27, 1906.

Tabes Dorsalis in a Negress.—The rarity of this disease in colored women leads W. G. Bowers to report a typical case occurring in a negro woman. He has been able to find twenty-one reported cases in this race, fifteen men and six women. The history presents no peculiar features. The patient was a woman of fifty-three, with symptoms dating back three years. She was in the hospital three and a half months and finally died from cystitis and sepsis following bed-sores.

What May Be Accomplished with Apparently Hopeless Cases of Tuberculosis.—Ten cases are reported by S. G. Bonney. They go to demonstrate the following propositions: (1) They are selected merely to illustrate the possibility of arrest in far-advanced cases. (2) The cases here described represent not simply what might be regarded as decidedly unfavorable cases, but were considered without exception, by other physicians as well as the author, as being utterly hopeless by virtue of every consideration which may ordinarily influence prognosis. (3) With the exception of the three cases, which are of very recent origin, the remaining seven have not simply undergone improvement with the ultimate outcome as yet uncertain, but have actually experienced a complete arrest of the tuberculous trouble, with entire absence of physical signs, sputum, and bacilli, with a complete restoration to former usefulness and activity. (4) The necessity for the practice of strict economy has been no insuperable barrier to the acquirement of complete arrest in a suitable climate and under proper régime. (5) No claim is made that the results obtained were entirely referable to climatic influences. It is contended, however, that such results in equally desperate cases are impossible of attainment in what may be regarded as relatively unfavorable climates, no matter how perfect the régime. (6) No special methods of treatment were employed other than those familiar to every physician of experience in the management of pulmonary tuberculosis. (7) No credit for results obtained is assumed other than that which may relate to an unremitting personal attention to detail, according to the exigencies of the situation and an adaptation of means to ends at times somewhat radical. (8) No case is here reported that is not entirely subject to confirmation by the attending physicians whose names are not cited in the report.

The American Aborigines from a Hygienic Standpoint.—A. L. Benedict presents an interesting study of the early history of the Iroquois and the Confederated Five Nations. They were not nomadic and not pastoral. Most of them lived jointly by hunting, fishing, and the cultivation of some of the more common vegetables. The degree to which vegetable food was used varied greatly according to local customs, soil, fertility, and the state of peace or war. Tobacco was obtainable only by barter and in small quantities. Willow bark was smoked to some extent, but smoking was not common. Alcoholic drinks were practically unknown until introduced by the whites. Semi-starvation alternated with gourmandizing. Almost all animal food was eaten well cooked. As a rule, permanent dwellings, as we understand the term, were not used. Small communities existed, but their location was changed from time to time, according to the need for firewood. Whenever a village was destroyed by fire, war, or any epidemic occurred, the site was permanently abandoned. As a rule these Indians manifested a considerable practical knowledge of sanitary science. Their villages were well located with reference to sandy soil, good drainage, good brooks for fishing, etc. Burial places were placed at a safe distance, and not more than twenty skeletons have been found at any one place. These people were not prolific. Few remains of small children have been found.

Sclerosis of the Coronary Arteries.—Harlow Brooks presents the results of a study of 270 cases noted in 1,000 consecutive autopsies. The disease may occur in comparative youth, being then amenable to treatment, and is not to be looked upon as a purely senile change. The average age of the author's cases has been about forty-five years. The abuse of alcohol appears to have been the most common exciting agent. The next most common cause is nephritis. Then comes syphilis. Other causes have been tuberculosis, cancer, diabetes, rheumatism, and myelitis. Overwork as a causative factor

has probably been overestimated. The conditions producing gout and rheumatism may lead to coronary thickening. The most common type of the disease is that of an endarteritis in which proliferative alterations are introduced in the subepithelial layer of the intima, although certain cases appear to show primary pathological changes of the adventitia in the greatest degree. In the author's experience true arteritis is rare in the coronary arteries. The most frequent change in the heart muscle was fatty degeneration. All the 270 cases except fifteen showed lesions of the myocardium visible to the unaided eye. Brown atrophy was noted in sixty-four; fibrosis was found in twenty-four; hypertrophy was noted in thirty-five; actual dilatation demonstrable on post mortem was presented in twenty. The author discusses the symptoms of the disease and passes on to consider treatment. In early cases, when the condition may be presumed to be present, though not absolutely demonstrable, hygienic measures are of great service. All mental and physical excesses must be avoided. Causative factors must be eliminated as far as possible. Diet must be regulated for each individual case. In the advanced cases which call for the use of medicinal remedies probably the best one at our command is the iodides. When vasodilatation with sedation is required strontium bromide is of great service. Chloral is often satisfactory in this direction. When immediate vasodilatation is required amyl nitrite is the choice. When the myocardium begins to degenerate drugs of the digitalis type are indicated. They must be used cautiously, however, or there may be a danger of fatal arterial spasm. When rapid heart action is present, rest in bed, morphine, and the icebag become imperative. Rest, however, may in some cases be enforced to an injurious degree.

Indications for Surgical Intervention in Diseases of the Stomach.—J. A. Blake divides operations on the stomach into three classes: First, repairs of wounds and perforations; second, improvement of drainage; and third, partial excision. In the first class surgical intervention is immediately indicated. In the second class the only conditions that can be helped are those which interfere with the normal drainage of the stomach. Such are pyloric obstruction, intermediate obstruction, or hour-glass stomach and ulcer. If there is evidence of pyloric obstruction we should not wait for evidence of a tumor, diminished hydrochloric acid, or dilatation of the organ. Hour-glass contraction always requires surgical intervention. In ulcers we may have acute or chronic conditions. In general the former call for medical and the latter for surgical aid, but we must be careful to understand just what is meant by these terms. Perhaps the designations of "early" and "late" would be better. Pyloric ulcers may be excised or treated by gastroenterostomy while cardiac ulcers must be excised. In the third class of cases the author states that when the pylorus with only the adjacent portions of the stomach and duodenum is removed, the operation is known as pylorectomy, while partial gastrectomy usually infers the removal of the pylorus with a considerable amount of the stomach. When only a small part of the stomach wall, such as an ulcer, is removed the term excision is employed. Carcinoma is the main indication for pylorectomy and partial gastrectomy, but not infrequently the pylorus, with the adjacent portion of the stomach, should be removed for ulcers, particularly when large or multiple; in fact, as has already been stated, on account of the possibility of malignant degeneration, the excision of ulcers when practicable is always indicated. In cancer of the stomach there is no question as to the propriety of operating, unless we feel certain that it has advanced so far that there is no hope of good even from a palliative operation such as gastroenterostomy. The author then discusses points of differential diagnosis and shows by collated statistics that the mortality of these extensive operations is steadily lessening. He does not think that we should refuse operation in any case in which there is a chance for benefit, particularly when stomach drainage is being interfered with.

American Medicine, August and September, 1906.

Influence of Rest, Exercise, and Sleep on Gastric Digestion.—Julius Friedenwald, from his observations draws the following conclusions: In persons with normal digestive powers it makes but little difference whether the individuals rest, exercise, or sleep after meals, though after violent exercise or sleep the gastric digestion is very slightly impaired. In patients suffering with superacidity and subacidity it is best to order rest after meals; after violent exercise or during sleep the digestion is impaired in these cases. In patients suffering with motor disturbances of the stomach it is best to prescribe moderate exercise after meals, for rest, violent exercise, or sleep disturbs the digestion under these conditions.

Multiple Chancre.—A. F. Büchler states that while the initial lesion of syphilis is generally single, in a goodly proportion of cases it is found to be multiple. The results of the writer's investigations show that in the two hundred and seventy-three cases of initial lesion of syphilis recorded in recent years, thirty-three, or a proportion of more than twelve per cent. were of the multiple form. Of these thirty-three cases, in twenty-five there were two lesions, in six there were three, and in two there were five. The multiple lesion, according to the writer, was either purely genital, purely perigenital, or purely extragenital in location. In the first group there were thirty cases, in the second one, while two lesions were extragenital in position. Numerous well-attested examples of combinations of these groups have been recorded. As to the mode of evolution of the multiple lesion, the histories here reported are incomplete. However, the development of the chancres in most of the cases was said to be synchronous. In a number of instances the evolution was successive. The interval between the appearance of the first and the successive lesion or lesions, with the exception of one case, never exceeded a week. The writer believes that in the negro the dual chancre is the rule.

Treatment of Cancer of the Breast.—Beverly MacMonagle presents these conclusions: All tumors of the breast are a threat to the well-being of the patient. Positive diagnosis cannot be made in the early stages without microscopic aid. All tumors of the breast should be removed with care to prevent reinoculation. Microscopic diagnosis should be made. This should be followed at once by radical operation if the growth is found to be malignant. This method gives the best chance of improving the results of surgical treatment of cancer of the breast.

Pernicious Effects of Alternating Currents of High Voltage.—Frederick H. Millener has recently made careful investigations in twenty-four cases of individuals suffering from the pernicious influence of the alternating current, especially when of high voltage. He calls attention to the well-known fact of the souring of milk immediately after a thunderstorm. In dairies in which separator machines are used the direct current is invariably employed because souring of the milk does not occur when this is used instead of the alternating current. The writer describes a patient who worked in one of the power plants. These plants are kept scrupulously clean, but the patient in a short time had lost his appetite, his face and hands had become almost chalky white, and his condition was becoming serious. The writer then asks what this mysterious force is which flows through the atmosphere. The other patients whom he has examined show symptoms similar to those here described. He believes that the condition is due to the effect of the alternating current of high voltage. He presents this problem, the solution of which he cannot predict. If a man thus disturbed should apply for life insurance he would be put in the substandard list. This problem is sufficient to warrant further study and investigation.

Scarlet Fever.—Joseph F. Chmelicek Luhan in the last five years has not lost a patient with scarlet fever, nor among his 129 patients has there been a serious complication. He believes that the condition of the blood is the direct cause of cardiac paralysis, to which death is due in so many cases of this disease, especially in children. He isolates the patient in the lightest and best room in the house. A warm bath is given and the bowels are relieved by an enema or magnesium citrate. The patient is kept on a strict diet of milk, with plenty of water and soups. Antipyretics, excepting the tepid bath, are not used. Elixir of sulphocarbolate of iron is prescribed up to the fourth day; after this, elixir sulphocitrate of iron is administered for four days.

The Making and Dressing of Wounds.—Miles F. Porter declares that wounds should be as small as may be compatible with accurate, reasonably rapid work. He concludes his paper with the following statements: Unwise efforts to produce asepsis may cause more harm than the bacteria against which they are directed. The surgeon's attitude toward nature should be that of a modest cup-bearer, not that of a usurper. Sutures, redressings, and drains are, at best, necessary surgical evils; hence, all sutures should be discarded in favor of the bandage and adhesive plaster when these can be made to serve the same purpose, but when the use of

sutures is imperative, then (a) buried absorbable sutures should be preferred; buried nonabsorbable temporary sutures should be the second choice; through-and-through sutures should be used only on compulsion, and buried permanent sutures should be discarded except in work on the hollow abdominal viscera; (b) the physician's aim should be to do the first dressing so that it will be the only one needed until healing is accomplished, and, when this is impossible, efforts should be directed toward preventing the necessity of frequent dressing; (c) when in doubt, the physician should not drain, but, if drainage is imperative, it should be adequate without being harmful, kept up while it is needed, and discarded so soon as it has fulfilled its mission.

The Relation Between Tonsillitis and Acute Articular Rheumatism; with Particular Reference to the Prophylaxis of Postanginal Rheumatism.—Charles F. Kieffer has studied the retained records of Fort Russell for a period of thirty-eight years. These records show 2,275 cases diagnosed as acute tonsillitis. In the same time there were 1,293 cases diagnosed as acute articular rheumatism. The records seem to indicate that the epidemic or infectious form of tonsillitis is followed in a large proportion of cases by rheumatism. In these records 276 cases of articular rheumatism were preceded by tonsillitis, a proportion of 21.3 per cent. The extreme incubation period varied between three days and thirty days, with an average of twenty-four days. The writer has had excellent results in the prophylactic treatment of postanginal rheumatism. On admission, the patient is given a full mercurial purge; the throat is then gargled with a saturated solution of sodium bicarbonate. Then finely-powdered acetyl-salicylic acid is rather firmly applied to the tonsil with a cotton-tipped wooden probe. Applications are made thrice daily. In the series of patients treated in this way not one case of rheumatism developed.

The Use of Nauheim Baths for the Failing Heart of Acute Infectious Diseases, Especially in Pneumonia; with Studies of the Blood-Pressure.—Philip King Brown says that under the immediate influence of Nauheim baths for chronic heart troubles there is a slowing of the respiration, a slowing in the heart rate, an increase in the volume of blood in the peripheral arteries, with a corresponding increase in arterial tension, and in the amount of urine eliminated. The writer has studied the effects of these baths on patients who were suffering from pneumonia. The pulse, respiration, temperature, and blood-pressure were taken before the bath. A full-strength bath was given at once. In practically every instance there was a lessening in the pulse and respiration rate, and a rise in the blood-pressure. In a few cases the effect of various drugs on the blood-pressure was compared with the effect of the baths. In every instance the average blood-pressure was higher and better sustained on the days when baths were given than on the days when drugs were given. The writer believes that the supplemental use of drugs is not to be neglected.

Treatment of Pneumonia.—Woodbridge Hall Birchmore declares that after the intestinal tract is emptied and cleansed and carefully maintained in satisfactory condition, nutrition will not be seriously interfered with. The body can then supply the needed strength for the healing process. To combat the cough ammonium chloride and the mixtures of the bromides have been found of the utmost use. The control of the circulation is best accomplished by the combined use of aconitine and digitaline. The latter causes contraction of the pulmonary arteries, while the former relaxes the systemic blood-vessels. If there is insomnia the writer believes that hyoscine is the best hypnotic.

An Unusual Case of Tic.—Alfred Gordon reports this case. The patient, a man twenty years old, exhibited peculiar forward movements of the trunk. These movements consisted of abrupt, spasmodic, and repeated bending forward of the upper half of the body over the lower. The contraction was found to be limited to both recti muscles. The tic was exclusively abdominal and in the domain of the recti muscles. No other part of the body was involved. The treatment suggested was chiefly psychic.

Journal of the American Medical Association, Nov. 3, 1906

The Dangers of the X-Ray.—D. L. Edsall's study of this subject during the past eighteen months has shown that the rays have effects on metabolism, in some instances most violent, occurring even in normal individuals, and that these are apparently present whenever a general influence is clinically observable. These metabolic changes are due largely, if not entirely, he thinks, to tissue destruction as shown by a relatively large output of uric acid, purin bases, and phosphates, indicating the excess of nucleoproteid destruction. Histologic studies by Warthin and others show that the organs most affected are the bone marrow, spleen, and lymphoid tissues. Edsall says that the effects of a single dose may be more severe than those of a similar dose of any other therapeutic agent with which he is acquainted, and may be either very useful clinically or so dangerously violent as to hasten death, or even to cause it where it might otherwise have been avoided. He has known of two deaths from this cause. He thinks we will have to recast our views somewhat; instead of considering the *x*-ray as an agent only secondarily and somewhat distantly harmful, we should recognize in it an agent as effective as a powerful drug, and one not to be used without good and sufficient reasons and with all needed precautions against its doing any possible harm. The *x*-ray specialist, moreover, should be fully informed as to all possible contraindications, so as to be able to employ reasonable caution in his applications. Edsall compares the *x*-ray to anesthetics, which no one thinks of recommending without due consideration of their possible dangers in any particular case. He mentions two groups of disorders that seem to him to deserve more careful consideration in this connection than others. One of these is nephritis; the other includes patients suffering from any serious degree of toxemia. A possible third group includes patients with decided anemia, especially if combined with toxemia. He believes that there are decided therapeutic possibilities in the action on metabolism of the *x*-ray, but it must be used with a definite appreciation of its restrictions.

The Effects of Pericarditis on the Heart.—N. S. Davis reviews the symptoms and lesions of pericarditis which are liable to be unrecognized because they are secondary in most cases to infections producing other symptoms that engross the practitioner's attention, especially when there is not much serous effusion. The myocardium is not apt to be seriously involved in acute or fibrinous forms of pericarditis, save in cases where the pericardial inflammation has complicated an already enfeebling condition. The effects of adhesions have no characteristic symptoms and rarely interfere with the functions of the heart to serious or even noticeable extent. The most trustworthy symptom is the unchanging shape of the area of precordial dullness during inspiration and expiration, which must exist when a pericarditis fastens the heart to the anterior wall of the chest. Adhesions are not usually very dangerous except in enfeebled conditions or after acute illness interfering with compensation. In most cases pericarditis is not fatal. From 50 to 75 per cent. of patients are estimated as recovering. Rheumatic pericarditis, as compared with that from other infections, is benign. Purulent and hemorrhagic pericarditis, unless recognized and successfully treated, is almost always fatal. A rapidly developed effusion is dangerous, but aspiration or treatment may produce recovery or a prolongation of life. A large slowly developed effusion is not threatening or immediately dangerous, and a small effusion is of no more gravity than fibrinous inflammation. About one-third of all cases are serofibrinous, about one-sixth are hemorrhagic or purulent, about one-twelfth tuberculous, and in an approximate number there is total adhesion, but in one-third there are partial adhesions. The condition of the heart muscle largely influences the prognosis. The chance of prolonging life is slight in cases of chronic alcoholism and the cachexias of cancer, Bright's disease, and tuberculosis. In these it is usually due to a terminal infection and is often the direct cause of death. It is also a much more serious complication with pneumonia than tuberculosis, and is a very grave complication with sepsis. Naturally, it is most dangerous at the extreme periods of life.

Angina Pectoris—True and False.—True angina pectoris, according to J. M. Anders, is a comparatively uncommon condition. Its mechanism is as yet imperfectly known, but two facts are generally acepted: 1. In the vast majority of cases it is accompanied with structural changes in the cardiovascular system; and 2, irritation or disturbance of the cardiac sensory nerves exists. He reviews the theories of its etiology and pathology and inclines to accept as probable the explanation of MacKenzie that impairment of the muscular contractility of the heart acts as an exciting cause

and elucidates many cases. An impaired nervous vitality must also be looked on as a predisposing cause. "But," he asks, "may there not be added peculiar nutritional or degenerative change in the nervous system, brought about by high nerve pressure, which finds its expression in a peculiar neurosis that serves as the predisposing element in angina pectoris?" Angina *sine dolore* must be accounted for, a condition, the main feature of which is an indescribable, almost painless, precordial oppression, that is not uncommon, engrafted on a variety of cardiac structural lesions. It shows that there is a distinction to be made between paroxysmal precordial pains and angina pectoris; the essential difference between true and false angina may yet be found in some at present unknown agency, or possibly in the different impairment of the muscular contractility, this being slight in the latter and carried to a dangerous extent in the former. False angina is characterized by precordial pain without the *angor animi* and without gross organic lesions, and it yields to appropriate treatment. Three groups are recognized, namely, the neurotic, the toxic, and the reflex. The latter class, Anders thinks, deserves consideration by itself, and the fact that certain contributing factors in true angina are present also in this variety renders it of special importance. The differential diagnosis between true and false angina is discussed and caution is suggested in making the diagnosis of the latter. Pseudoangina may develop into true angina, and it is safer for the patient to treat it as for the latter in dubious cases. There may be cases of true angina without apparent cardiovascular lesions, and in rare cases there may be an impossibility of their distinction. In spite of this and of the etiological affinities, Anders agrees with Huchard, Osler, and others in adopting this provisional classification and separating the functional from the organic forms whenever practicable. True angina is related to the functional forms so far as the vasomotor disturbances are concerned, but it also includes pathological lesions whose relations to the symptoms are truly obscure and complicated.

Appendicitis and Gallstones.—Attention is called by J. G. Sheldon to the apparent relationship existing between appendicitis and gallstones. From July 15, 1903, to July 1, 1906, he operated on forty-eight patients with gallstones, and on seven with appendicitis with cholecystitis without gallstones. In these seven cases his opinion was that the cholecystitis was secondary to the appendicitis. In two of the gallstone operations acute infection was present and the appendix was not examined. One of these patients is well, but the other complains of abdominal symptoms and has tenderness over the appendix. In the remaining forty-six gallstone cases the appendix was normal only in four, and in thirty-four of the others the history was plainly suggestive (and in some of them definite) of former appendicitis, dating back ten or twelve years. He reviews the evidence pointing to the origin of the infection causing gallstones, and deduces the probability of chronic appendicitis furnishing the germs through the blood stream. If the liver, through its inefficiency or from the number and virulence of the germs, is unable to dispose of them, and some of them are continually escaping into the bile stream, disease of the bile passages might occur. While this route is not definitely proven, it appears, theoretically and clinically, probable. Hence he concludes that disease of the appendix should be kept in mind in every gallstone operation. The appendix should be inspected when possible, and should by no means be considered normal on account of the absence of periappendicular changes. Unless Sheldon's experience has been altogether exceptional, he thinks that those who follow the above advice will be impressed with the frequent coincidence of appendicitis and gallstone disease, and that if the combined operation is done more frequently the results will be more permanent and satisfactory.

Sterile Salt Solution Injections in Intraperitoneal Hemorrhage.—M. Jampolis concludes: 1. The infusion of physiological salt solution into the peritoneal cavity should be practised in every case of hemorrhage not accompanied by infection, for two general reasons: (a) Its effect on shock; (b) its beneficial action on the peritoneum and the conditions in the peritoneal cavity; in some cases its effect would be palliative, in others, curative. 2. In cases of intraperitoneal hemorrhage accompanied by such severe shock as to render an immediate laparotomy necessarily fatal, the immediate infusion of warm physiological saline solution would certainly do no harm, but would stimulate the peritoneum, counteract existing shock, and prepare the system for any that might follow a subsequent operation. 3. If hemorrhage had ceased and laparotomy was not required, it would be of the utmost value. Besides combating shock, the solution would mingle intimately with the blood, hold the particles in suspension, and hasten absorption without permitting clots to form to be the basis of troublesome and dangerous adhesions. 4. The procedure requires no great skill and can be carried out by any general practitioner.

The Lancet, October 20, 1906.

Some Observations on Enlarged Veins in Children.—Fourteen cases are detailed by A. G. Gibson. He notes the finding of enlarged small veins on the chest and elsewhere in certain hospital cases with general debility, wasting, and listlessness. On the chest they appear as small ramifications flush with the surface of the skin; in front they tend to converge toward the upper part of the sternum, but behind they usually show a stellate arrangement. In some of the most marked cases large veins can be seen as far out as the deltoid region. As a rule no veins are seen below the chest, but the author has seen cases in which there was no abdominal disease showing such venules about the groin. The jugulars can almost always be seen either as blue streaks or distinctly dilated; one or both sides may be affected. Veins can frequently be seen also under the chin, at the temples, and very occasionally on the forehead. A normal adult from a number of causes may present a full jugular vein, but in very few children with no suspicion of disease is such a condition seen. In adults a large jugular vein is always emptied during inspiration, a fact which can most readily be verified by watching the neck of a person breathing deeply under ether; but in children who have large jugular veins together with venules on the chest a deep inspiration produces only a slight collapse, if any, of the veins; this is true of the upright as well as the recumbent position. The cause of this venous distention is undoubtedly tuberculous enlargement of the bronchial glands. Probably in most instances the mediastinal glands are similarly affected. The author notes that we have as yet no absolutely positive means of detecting minute glandular lesions of the mediastinum, so frequently the cause of a general infection, and suggests that the presence of visible veins on the chest, dilated jugular veins which do not collapse on inspiration, visible veins under the chin or on the temples, together with the other suggestive facts (enumerated above) in the history and state of the patient, may lead to an increase in the number of these cases diagnosed during life. It is hardly necessary to mention how quickly these children improve under a liberal diet and ordinary attention to health, and therefore what a valuable weapon for prophylaxis the knowledge of the presence of mediastinal tuberculosis may become.

A Method of Taking Impressions of the Weight-bearing Surface of the Foot.—W. D. Lawrie refers to a method recently suggested by Schüman of Leipsic. Two solutions are used, one of ferric chloride and the other a 5 per cent. solution of ferrocyanide of potash. It is found that it is difficult to handle the iron paper on which the foot rests and to distribute the ferrocyanide solution evenly over the foot. The author has therefore substituted the following method: The materials required are a glass slab, say 16 inches by 13 inches, a roller, and a tube of specially prepared printer's ink. A thin film is pressed out on the glass plate by the roller, and after standing on this the patient transfers his blackened sole to a sheet of paper. It is important to see that the patient puts his weight on the foot during both parts of the process. The result is an accurate and permanent impression of the weight-bearing portions of the foot. The foot can be easily cleaned with soap and water. The impressions may be photographed and reduced in this way to a size suitable for the notebook. Illustrations are shown from photographs of such impressions. A normal impression is by no means the rule. One picture shows the result of wearing high-heeled boots, viz., pes cavus with crowded toes. Another picture illustrates a case of flat foot. The method is inexpensive and easy of application.

Oral Sepsis in Operation on the Throat.—W. Wingrave makes a plea for putting the mouth in as favorable condition as possible before throat operations are undertaken and for the maintenance of this condition during the period of healing. Most cases do well under

ordinary circumstances, but there are some patients in whom the tonsil "stump" is very unhealthy looking, disinclined to heal, and complicated with middle-ear infection and constitutional symptoms. These are almost invariably the subjects of oral sepsis, malnutrition, or neglected sanitary measures—personal and with reference to home surroundings. The nasopharynx is normally sterile, but not so in the ordinary adenoid case. As a rule the less an infant's nose is interfered with, the better. Anterior or posterior nasal douching are not to be recommended. He advises the use, in twelve to twenty-four hours after operation, of a 1 per cent. solution of Peruvian balsam in albolene blown into the nostrils. Carious teeth should be removed. He mentions a long list of remedies which may be used in the mouth by gargling or with young children by the mouth douche.

A New Aspect of the Pathology and Treatment of Leprosy.—R. S. Black calls attention to the condition of the nose and nasopharynx in leprosy. For a long time he was puzzled to account for the marked chemical difference between the maculo anesthetic and nodular forms of the disease. It finally occurred to him that the nodular and mixed forms were simply the maculo-anesthetic form plus the infiltration and edema of the subcutaneous tissue in various areas caused by the active invasion of the bacillus lepræ. In practically all cases of nodular leprosy anesthesias and leucodermic patches can be found just as in maculo-anesthetic leprosy. He also noticed that when a nose had fallen in in some cases of nodular or mixed leprosy the type of the disease in the individual seemed to change and he became practically in course of time a maculo-anesthetic case, the infiltrations being gradually absorbed. He further noticed that some cases of undoubted maculo-anesthetic leprosy were of an extremely mild character. A patient would have a few anesthetic patches on his body with, perhaps, a contraction of the small and ring fingers of one of his hands and would otherwise be in perfect health—in which condition he would remain for years. He also found that practically all the active cases of mixed and nodular leprosy suffered from rhinitis and were discharging bacilli with the nasal secretion in great numbers, whereas except in a few of the early cases he found that the maculo-anesthetic patients had no bacilli in their nasal secretion. The above considerations afforded him what he considered to be a solution of the problem. He thinks that there can be hardly any doubt that leprosy in its early stages begins as a small ulcer on some part of the extensive nasal mucous membrane. We know quite well from our clinical experience of the disease that leprous ulcers in favorable circumstances tend to heal. There can therefore be little doubt that a person can suffer from a leprous ulcer in the nose that may heal and pass entirely away. This is the explanation of the maculo-anesthetic cases. They have had nasal ulceration which has passed away, in some cases leaving perhaps a cicatricial shrinking of the nasal septum, but during the time the ulcer existed leucocytes or white connective tissue corpuscles got detached from the ulcerating spot and along with the bacilli which they were attempting to devour were carried by the blood stream and lodged in various situations in the peripheral nerves, where they got entangled, and the bacilli then proceeded to grow, causing pressure on the fine nerve fibrils and consequently setting up nutritive changes in the skin which these axis-cylinders supplied, thus causing the patches of discoloration and anesthesia. The corollary from this theory of etiology is that if the disease can be recognized in the nose in its early stages, the treatment can be brought into line with that of tuberculosis and diphtheria. We must destroy the local nidus before the system at large becomes infected. He also thinks that the opsonin theory of Wright may be applicable to the therapy of leprosy. This possibility is made more promising by the fact that the *Bacillus lepræ* seems to be a surface growth and that it takes a very considerable time to become established in the body.

British Medical Journal, October 20, 1906.

The Influence of Early Feeding in the Treatment of Typhoid.—F. J. Smith would avoid hard, indigestible, and sharp-edged seeds of such fruits as nuts, grapes, oranges, strawberries, figs, etc., but does not object to giving the strained juice of such fruits as are juicy enough for the purpose. Moreover, he would avoid giving any food too freely or injudiciously, but he does not interdict a bit of bread and butter or an egg simply because a patient's temperature is not absolutely normal. He has on record a series of 113 cases with twenty-four deaths occurring in hospital practice, but of the deaths but four took place after solid food had been given. The remaining twenty had received no solid food. He compares his own cases with those of the other physicians in the same hospital. His own patients were placed on food (bread and butter or rusks, fish, and meat) and were fed about two weeks earlier on the average than the cases of his colleagues. His own cases had 2 per cent. of complications (venous thrombosis, peritonitis, and abscess formation), while the collective cases (1,429) of his colleagues showed 10 per cent. of complications. This remarkable immunity of the "early-fed" cases can only be explained by the better resisting power of the patients. The less frequent occurrence of thrombosis (Smith 1 in 113, colleagues 59 in 1,429) may be accounted for by the fact that the author's cases had a diet containing less calcium than the patients obtained on the ordinary milk diet. Early feeding seems to have but little effect on the occurrence of relapses. Other interesting points of comparison are given.

The Treatment of Typhoid Fever.—The paper by W. B. Thistle is an inquiry regarding the effect of purgatives on the intestinal lesions of typhoid. He believes that the battle is mostly won or lost in the first week of the disease. If nothing is done to limit infection of the glands or of the body, the result is a matter of chance. He believes that the judicious use of purgatives greatly limits the number of bacilli gaining access to the intestinal glands, and thus limits the destructive process in them. He has never encountered during the period in which he has relied on purgation a fatal perforation or hemorrhage. As soon as a case comes under his care he sweeps the intestines clear as quickly as possible with purgatives, giving usually a few grains of calomel followed by half an ounce of some saline. He repeats this process day after day, the object being twofold. First, to prevent additional infection of the intestinal glands, and, second, to abstract toxins from the body by way of the bile stream and the intestinal secretions. The time to cut off or attack the bacilli is, of course, before they are carried to the glands; while they are in the drainage area, which in the case of the intestinal glands is the intestinal mucosa and the intestinal contents. If purgatives are freely and frequently used, and are efficient in the early period of typhoid infection, it must be that many bacilli are removed from the drainage area that would otherwise go to increase the number already in the glands. If the purgative is repeated day after day and at the same time an antiseptic is given, the effect, in so far as the drainage area of these glands is concerned, is identical with the surgical procedure of bathing an infected surface with an antiseptic lotion. The good effect upon the glands is due in both cases to the removal of bacilli from the drainage area, and the consequent curtailment of bacterial infection in the glands.

Spirochetes in Yaws and Granuloma Pudendi.—A. MacLennan records the findings in some smear preparations from yaws. The smears were fixed in methyl alcohol and were stained in a number of ways. In one specimen taken from a papilloma in recurrent yaws numerous spirochetes were observed. The method of staining was by Giemsa's solution and gentian violet. These spirochetes possessed similar characters to those of the *Spirochæta pallida,* but the staining was fainter. Loops in the course of the filament were observed, as in the pallida. In two smears from *Granuloma pudendi* he has found a few spirochetes—most probably the refringens—while in one stained first in fuchsin, then in acetone gentian violet, a number of very long highly-refractive spirochetes were observed. These parasites were much longer than the *Spirochæta pallida,* and the waving was finer and closer. In one forty waves were counted. Though the staining was very prolonged, these spirochetes were very faintly stained. There were also a number of other structures present which were less definite.

The Management of Advanced Cases of Heart Disease.—This subject is considered by R. Saundby under the headings of exercise, Schott treatment, diet, heart tonics, vasculodepressant remedies, bleeding and leeching, tapping, purgation, oxygen inhalations, and hypnotics. We can refer here to only a few of the many practical points he suggests. He gives a high commendation to the baths and exercises of the Schott system, though attaching no importance to the presence of free carbonic acid gas in the water. Rest is called for in a more or less recumbent position: (1) When

more or less dropsy is present; (2) when walking brings on severe dyspnea or pain, and (3) when the circulatory condition is so bad as to cause danger of syncope. Digitalis is the best of the heart tonics. Next come caffeine and theobromine. Nux vomica and strychnine should not be held back until the patient is *in extremis*. Erythrol tetranitrate is his favorite vascular depressant in half grain doses (tablet) every four hours. It occasionally causes severe headache and must be withheld. It may be given alternately with digitalin. For purgation he prefers elaterum. Oxygen inhalations may be tried, but Saundby has little faith in their efficiency. They may be ordered for patients who are in a hopeless condition to satisfy the desire of the friends that something should be tried, but the difficulty being not to get air or oxygen into the lungs, but to carry on the pulmonary circulation with greater rapidity, no advantage accrues to the patient from a higher proportion of oxygen in the air inhaled, as only a definite amount of oxygen can be taken up by the blood, and this is determined not by the quantity present, but by the state of the circulation.

Berliner klinische Wochenschrift, October 15, 1906.

A Contribution of the Serum Treatment of Syphilis.—Engel describes observations made in three cases of syphilis treated by means of injections of an autoimmune serum obtained in the following way. About twice a week 10 cc. of blood was taken from the forearm of the patients, and after heating for half an hour in order to inactivate the complement was injected into the peritoneal cavity of a rabbit. After twelve injections the rabbit was bled from the ear on ten different occasions and from 1-5 c.c. of the serum obtained was injected under the skin of the arms or backs of the patients. Each injection was followed by a sharp local and general reaction. All of the lesions subsided, apparently in consequence of the treatment, and there have been no fresh manifestations during several years. The author describes hemolytic and other tests of the serum produced which lead him to believe that it really contained antibodies, and he suggests that other diseases such as pernicious anemia and some forms of nephritis may be amenable to treatment carried out along the same lines.

The Early Diagnosis of Syphilis.—Danziger is of the opinion that the spirochete question has reached a stage of development which renders it available in the early diagnosis of primary syphilitic lesions. He gives the histories of five cases in which it was possible to identify spirochetes in secretion obtained from genital lesions whose character was still indeterminate and which subsequently developed into chancres. He therefore urges that this method be applied more generally, though he points out that only a trained observer can give a reliable opinion as to the nature of any organisms that may be discovered.

Münchener medizinische Wochenschrift, October 16, 1906.

The Treatment of Fresh Wounds with Dried-Out Dressings.—Asbeck considers that attempts to disinfect fresh wounds are ordinarily ill advised, for in general it may be said that all such may be regarded as not being seriously infected. It is, therefore, unnecessary and even injurious to attempt to cleanse or disinfect such a wound, for it is impossible to wash out or kill any germs that may be present without at the same time impairing the vitality of the body cells. Naturally, any visible particles of foreign matter must be removed. Disinfection and cleansing of the surrounding parts causes the uper layers of the skin to became softened and washes infectious organisms into the wound. The method which he has employed in over 500 cases of fresh injuries consists in covering the wounded area with a compress of gauze impregnated with iodoform or with some of the newer substitutes for this without any preliminary cleansing operation. Plain gauze and absorbent cotton are placed over this and the dressing is completed with a gauze bandage. These procedures are carried out under aseptic precautions. The injured part is then exposed during a period of from one-half to three-quarters of an hour to the radiating heat emanating from some powerful heating apparatus, in factories or forges, the furnaces being used, and in household practice, the kitchen stove. For small injuries the Bunsen burner may be used. When the dressing is to be changed the removal of the adherent gauze is facilitated by the use of peroxide of hydrogen. The rapidity of healing and the freedom from complications under this treatment are said to be astonishing.

The Technique of Skin Grafting.—Waljaschko says that none of the various substances in common use for dressing cases of skin grafting satisfactorily fulfill the requirements of facilitating healing of the wound and of immobilizing the grafts. He has found the following method very satisfactory: A piece of tulle a little larger than the denuded area is boiled in soda solution and wrung out in sterilized gauze. It is then spread over the grafted surface and its edges are cemented to the surrounding skin by means of collodion. The ordinary dressing of sterile gauze is then applied. In order to prevent maceration of the grafts they are never applied overlapping each other, and they also must not overlie the skin at the wound edges. The gauze outer dressing is changed daily, but the tulle is not removed until the tenth or twelfth day. The tulle dressing is particularly advantageous in maintaining the grafts in position in difficult situations such as the chin, the jugular fossa, between the fingers, etc.

Deutsche medizinische Wochenschrift, October 18, 1906.

Hydrocyanic Acid Poisoning.—Tintemann describes an instance of poisoning by hydrocyanic acid which though followed by serious symptoms did not terminate fatally. A young student of chemistry, at the conclusion of some work with this acid in cleaning the test tubes used, allowed one of them to fall into the sink, and in bending over to pick up the fragments inhaled the hydrocyanic acid fumes. He was instantly seized with extreme dizziness so that he saved himself from falling only by grasping the water faucet. After about a quarter of a minute the dizziness grew less and the patient was able to seek the open air, hoping that this would bring relief. Instead of this, severe cardiac oppression, palpitation, and dyspnea appeared so that he was forced to go to bed. It was not until nine days later that the urine became free from albumin and casts, and the temperature remained elevated for about a week. Other symptoms that were prominent during this period were great unrest, obstinate insomnia, severe headache, and total distaste for food. In discussing the case the author lays special stress on the parenchymatous degeneration of the kidneys that was caused and on the elevation of temperature. The former important complication he says has heretofore not been observed or at least has not been reported.

Further Observations on the Penetrating Action of the Hot Water Alcohol Method of Hand Disinfection.—Ahlfeld endeavors to refute the contentions of his opponents by citing further statistics obtained in his obstetrical clinic at Marburg. Krönig, in referring to the particularly strict asepsis of the Leipsic clinic, notes that after the omission of all operative cases and some others, in 2,094 labors a mortality of 0.1 per cent. was recorded, and that in a series of 980 normal cases there was a puerperal morbidity of 42 per cent. Ahlfeld, during the last year, has had in all 750 deliveries, with no septic deaths and a morbidity of only 29.7 per cent. These figures include all cases, operative deliveries, placenta previa, eclampsia, and cases infected on admission. During this period six courses of instruction have been given to midwives and others, so that in addition to the regular staff 200 to 250 other persons made vaginal examinations of the patients. Ahlfeld has the conviction that if his method of sterilizing the hands is used no appreciable danger attends vaginal examination. He gives the detailed statistics of about 3,500 cases, different groups of which were examined 1-5 times, 6-10 times, and 11-15 times, respectively. The percentage of morbidity in the first group was 30.24 per cent., in the second, 31.85 per cent., and in the third, 28.89 per cent., the standard of morbidity being any elevation of temperature over 38° C.

The Extraction of the Torn-Off After-Coming Head.—Borginis says that although owing to the greater frequency of forceps operations, the practitioner is now, fortunately, seldom in the unpleasant position of being obliged to remove a head from which the body has been torn, this condition must still sometimes be dealt with. In some cases in which the usual methods fail he has found the following procedure very useful. The head is fixed from without through the abdominal wall and is then grasped securely with a volsella or similar type of clamp passed through the cervix. To the end of the instrument projecting from the vagina a cord is attached leading over the foot of the bed and having a weight at its extremity. In the course of a comparatively short time the cervix will be sufficiently dilated, even in cases in which considerable contraction had already taken place, to enable the head to be removed without great difficulty by the application of forceps.

Book Reviews.

On Leprosy and Fish-Eating. A Statement of Facts and Explanations. By Jonathan Hutchinson, F.R.S. and F.R.C.S.; LL.D., etc. London: Archibald Constable and Company, Ltd.; Chicago: W. T. Keener & Co., 1906.

The object of Mr. Hutchinson's book is to present facts, statistics, and documentary and other evidence in support of his conviction that "the fundamental cause of the malady known as true leprosy is the eating of fish in a state of commencing decomposition." The author limits his accusation distinctly to bad fish, adding that the fish supplied in the English market is "obviously quite free from the risk of causing leprosy." He believes that the cause of leprosy is some product of decomposition or some parasite present in decaying fish. The free use of salt in communities where fish is eaten in large quantities is the best preventive of the disease. The author has devoted to the study of leprosy a great deal of his time since 1855. In 1863 he wrote a paper in which he foreshadowed most of his present conclusions, and his research in this line, including travel to various parts of the world, has been unremitting. The work practically represents a life-long study of leprosy from the viewpoint indicated. The book contains a mass of most interesting material, carefully and systematically collated, and pleads the cause most eloquently, though unconvincingly. It is a curious instance of a man sticking to a theory against reason and against facts.

Diet and Dietetics. By A. Gautier. Edited and Translated by A. J. Rice-Oxley, M.A., M.D. Philadelphia: J. B. Lippincott Company; London: Archibald Constable & Company, Ltd., 1906.

In this work the translator has made accessible to English readers the painstaking but by no means original work of Gautier. The book is, in fact, a compilation of the observations and views of the recognized authorities on dietetics up to about two years ago, and in view of the vast importance of recent contributions to the study of food metabolism, it is necessarily already somewhat out of date.

The author has divided his work into three parts. Part I treats of "Principles and Methods." After some general consideration of the mechanism of assimilation, normal proportions of the organic fundamental principles of ordinary alimentation, etc., he arrives at his conclusions as to the food requirements of the average healthy individual by an exhaustive study of the quantities and relative proportions of the food supply to the city of Paris for the decennial period, 1889-1899, and accepts the figures which thus represent what the average inhabitant of Paris *actually consumed* during that period as a criterion. Thus, he estimates that the healthy individual, under ordinary conditions of life, requires 110 grams albuminous food, 68 grams fats, and 425 grams carbohydrates. These quantities and proportions are practically those of the older accepted standards of Voit and others, and perhaps will in the end be found physiologically correct, but one is tempted to criticise the method employed for determination of this standard as unscientific and empirical.

In Part II the author discusses at considerable length the various aliments, and despite unnecessary wordiness and tedious discussion there is much of practical interest to be found in this part of the work.

Part III treats of the regimens applicable to varying conditions of health, age, and disease. The chapters comprising this part of the book will be found of least value to the American dietitian, since the regimens indicated in most diseases are made up largely with respect to "dietetic tastes" very foreign to those inculcated by American education.

The work as a whole, while tedious and somewhat boresome to read, and while failing to bring the subject up to date, nevertheless possesses merit, and must have a certain value for the dietitian of whatever country. Insofar the translator deserves credit for making it accessible to English readers.

Lectures on Midwifery for Midwives. By A. B. Calder, M.B., M.R.C.S., Lecturer on Midwifery to London County Council, to St. Mary's Midwifery Training School, etc. New York: William Wood and Company, 1906.

The author has collected in this book his lectures on obstetrics to classes of midwives, and the subject is therefore relieved from all details not pertinent to the aim expressed in the title. There is no class of women to whom the book could be directly addressed in this country, where no systematic control is exercised over midwives, but its contents are nevertheless instructive and valuable to American nurses who may be called upon to do obstetric work. The text is clear and easily read, but the illustrations leave something to be desired. The chapters on asepsis and sanitation are particularly good, and might be read with profit even by many a general practitioner.

Feuchtfröhliches und Feuchtunfröhliches. By Karl Beck. Berlin; Leonhard Simion Nachfolger, 1906.

Aside from his numerous technical contributions to medical literature, Dr. Beck has favored us with several entertaining publications which might appropriately be included among the belles lettres of medicine. The present work contains four descriptive articles on Heidelberg and its student life, and on Reichenhall and Carlsbad, the well-known European spas. Humor and pathos are intermingled in a way which compel the reader to continue to the end when once he has begun the book. These two qualities have prompted the title of the book, for which, however, no exact English equivalent can be given. It is a matter of regret that Dr. Beck's literary ability does not also find vent in a language that would assure a still wider audience among his American confrères.

The Prophylaxis and Treatment of Internal Diseases. Designed for the Use of Practitioners and of Advanced Students of Medicine. By F. Forchheimer, M.D., Professor of Theory and Practice of Medicine and Clinical Medicine, Medical College of Ohio, Department of Medicine of the University of Cincinnati; Physician to the Good Samaritan Hospital; Member of the Association of American Physicians, the American Pediatric Society, etc. New York and London: D. Appleton and Company, 1906.

There is a flavor of originality about this book that is most refreshing. The author tells what he himself has learned from experience, and what he himself does in his practice, taking his readers, as it were, to the bedside, and pointing out the indications for treatment, and how they can best be met. This does not mean, however, that nothing is said of other methods of treatment than the one specially favored by the writer, for Dr. Forchheimer shows himself possessed of a catholic mind which is willing to admit that the experience of others may count for something, and he accordingly mentions the modes of treatment, and the remedies which other practitioners have found useful, and leaves his readers free to choose them if they see fit. The book is not a treatise on the practice of medicine, but is, as its title indicates, devoted solely to prophylaxis and treatment. The reader is presumed to have made the diagnosis and to be acquainted with the pathology, and also with the etiology, though the latter is referred to so far as is necessary to explain the rationale of the prophylactic measures advocated. The work is well written in an easy style, concise, yet not unduly condensed, and thoroughly practical in every line.

While thus expressing our admiration for this book, and recommending it as a work of reference which should be on the shelf of every progressive physician, we cannot agree with all its teachings. This is merely saying that no man's work is perfect or above criticism. It is unwise, we think, to teach that a syphilitic is no longer a danger to his family in the tertiary period of the disease, for not a few syphilographers have expressed the opinion that tertiary lesions are sometimes communicable, and if the spirochete exists in these lesions, as some claim, the contagiousness of the disease in this stage must be acknowledged. Again, in the prophylaxis of dengue nothing is said of the agency of mosquitos in the transmission of the disease; yet writers on tropical medicine are coming to look upon this vicious insect as the possible, if not the probable, host of the extra-human form of the assumed protozoan cause. This is as yet problematical, but it is sufficiently plausible to call for mention in connection with the prophylaxis of this painful affection. A more serious omission is that in the section on the treatment of headache. The author deals with nervous headache, gastrointestinal headache, headaches due to circulatory disturbances, headaches in school children, headaches in adolescents, rheumatic headaches, and headaches for which no cause is discovered—and in all of them not a word about eyestrain! Whatever views may be held as to the teachings of extremists regarding the influence of eyestrain in the production of various reflexes—nervous, gastrointestinal, and even scoliotic—it is as certain that uncorrected ocular defects may cause headache as that vaccination will protect from smallpox, and it is most regrettable that the author of this work should ignore such a simple and absolute cure of many headaches, especially those afflicting school children and adolescents, as the correction of astigmatism and other visual defects by glasses. Fortunately, this defect in an otherwise admirable book will not have any serious consequences, since the laity, as well as the profession, is so aware of this factor in the causation of chronic headache that the first person consulted in such cases is usually the oculist. With this exception, the few other deficiencies which we have detected in a very careful examination of the book are of minor importance, and count but little in comparison with the sane and sound admonitions in every page of this admirable therapeutic treatise. To the recent graduate, especially, we commend the book as a safe guide in the treatment of disease.

Society Reports.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Sixteenth Annual Meeting, Held at Philadelphia, September 18, 19 and 20, 1906.

DR. WILLIAM BENHAM SNOW OF NEW YORK, PRESIDENT, IN THE CHAIR.

PRAYER was offered by Rev. Dean Groton and addresses of welcome were made by Hon. John Weaver, Mayor of the city; Dr. Charles K. Mills, President of the Philadelphia County Medical Society, and Dr. John V. Shoemaker of the Medico-Chirurgical College.

President's Address.—Dr. WILLIAM BENHAM SNOW of New York delivered this address, taking as his theme: "The Past, Present, and Future of Physical Therapeutics." From the earliest times, he said, experimental medicine had been the bane of both physician and patient, and in practice to-day views and methods were diverse. Physical agents in the hands of those trained to employ them would find an important field in future therapeutics because their indications and uses were rational. In their use as much depended upon the skill of the operator as in the case of the surgeon who operates with the knife. Those who rendered the most conscientious service in therapeutics were those who did not confine themselves to one line of treatment—drugs, surgery, electrotherapy, phototherapy, or any other means or methods—but made the best and judicious use of all. The call was for a broad gauge, honest, investigating spirit, and with a willingness to adopt all that was good and a determination to weed out the dangerous and spurious in therapeutics. Unfortunately the number in the profession who had made a conscientious study of electricity, radiant energy, heat and cold, exercise, mechanical vibration, and other physical measures, and had a fair conception of their value in therapeutics, were relatively small. Several general indications were to be observed in therapeutics: (1) prevention, (2) removal of infection and its effects—toxemia and congestion, (3) the removal of the effects of trauma—local stasis, and the products of inflammation, and (4) the establishment of functional activities. Noninfected inflammatory conditions arising from trauma or other irritation called for restoration of circulation and activity where stasis existed, for it was the inertia in the tissues thus established that rendered conditions chronic. For its removal mechanical measures were imperative. Static electricity, radiant heat and light, and the judicious employment of mechanical vibration met in various ways conditions of simple induration. For the relief of infected inflammatory processes, the removal of stasis was dangerous, except during the first days, when the total of infection was not so great that the leucocytes could not destroy it. The general principles involved in the treatment of infectious processes were drainage, increased leucocytosis, by increasing local vascularity, and the employment of dry hot air, radiant light and heat, the *x*-ray and the high frequency currents which destroy the germs *in situ*. The physical agents were invaluable in inducing the restoration of local and general metabolism, in removing contractures, regulating the vascular conditions, and reestablishing functional activities, thereby promoting necessary tissue building and elimination. The time had come and the rights of humanity demanded at the hands of the great profession to whose care their lives were intrusted, to eliminate useless measures, and to adopt and judiciously employ or prescribe only the best as indicated.

When Is Electrotherapy Indicated?—Dr. A. C. GEYSER of New York City endeavored to answer this question. Ignoring all fine technicalities, he explained what was meant by the term electrotherapy. From certain groups of ailments a few were selected and the rationale explained. It was not to be inferred that electrotherapy was "good for what ails one," or that it should be used to the exclusion of any other therapeutic measure. He emphasized the fact that of necessity the successful physician must first remove the cause; secondly, treat the patient and not the disease; and thirdly, before selecting any therapeutic measure, think and use common sense.

Dr. FRANCIS B. BISHOP of Washington, D. C., did not agree with Dr. Geyser that the wave current was a tonic, but that it was a stimulant. The question was raised whether or not cases of chorea required stimulation, since chorea was not always due to congestion of the cord, but to nutritive changes in the cord. In the treatment of nervous cases it should be remembered that they did not all respond to electrical treatment in the same way, and the current should therefore be suited to the condition of the patient. Neurasthenia, for example, the result of some infectious disease, would require different treatment than when produced by other conditions.

Dr. G. BETTON MASSEY, in answer to the reference to cataphoresis in connection with the *x*-ray, asserted that the zinc mercury cataphoresis would cure a case of very extended tuberculous infiltration of the glands of the neck.

A Plea for Conservatism in Electrotherapeutics with Remarks on Dosage.—Dr. A. D. ROCKWELL of New York City, in presenting this paper, called attention to the lack of judicial fairness revealed by a survey of the current literature of electrotherapeutics. As a result of this, the enthusiast became an altogether illogical pessimist and denied the efficacy of the agent that he had crudely tested, and upon the other hand there was an overconfidence characterizing every public utterance or written report. The one encouraging feature in the development of electrotherapy was said to be the fact that a fuller knowledge of physical methods led to a greater exercise of rational judgment in testing them. A good working knowledge of physics and a skilled technique were essentials mentioned in the application of electricity. The first broad general principle to be considered in the therapeutics of electricity was its influence over nutrition, and these nutritive effects, which were secondary, were regarded as far more valuable than the primary effects, whether they were stimulating or sedative. It was to be remembered that electricity might act as a stimulant or as an ugly irritant; or, in many an hyperesthetic condition of the nervous system, as a prompt and unequaled sedative. The necessity of familiarity with Ohm's law was also emphasized. Reverting to the fundamental idea of the nutritional effects of electricity, Dr. Rockwell emphasized the fact that its greatest value lay in its general application rather than in the local, thereby affecting either directly or reflexly the whole central and peripheral nervous system, including the entire muscular and circulatory system under their control. While fully recognizing the value of the newer modalities he accorded to general faradization an individual merit equal to any other of the general methods. An additional argument for its study and general use was its slight expense. The question of dosage was considered of special importance in its relation to the galvanic current, because of its chemical or electrolytic power and its profound influence upon the central nervous system, and because it was the only manifestation of electricity that was physiologically exact and whose slightest variation could be measured with absolute accuracy. In the use of the galvanic current for deep-seated neuritis, for the pain due to parenchymatous degeneration and internal cancer, and especially for exophthalmic goiter, massive doses were said to be necessary. To overcome the objections found in the use of sculptor's clay as an elec-

durance, but without injury to the skin. To overcome the objections found in the use of sculptor's clay as an electrode Dr. Rockwell had devised an electrode consisting of rimmed discs of hard rubber of any diameter desired, the bottom being covered with block tin, practically unoxidizable. Filled to the brim with the clay properly prepared it was ready for use.

Locomotor Ataxia.—Dr. Francis B. Bishop of Washington, D. C., described his technique in treating this disease. In the early second stage he had been able to give patients marked relief. In addition to treatment received at his office, they were instructed to carry out a series of exercises at home laid down by Fränkel.

Dr. F. H. Morse of Boston had seen cases of well-marked locomotor ataxia greatly improved by the use of the negative continuous current to the spine and by the general methods of improvement of nutrition.

Dr. J. D. Gibson of Denver thought the diagnosis of locomotor ataxia ought to be made before there was disturbance of locomotion. He cited a case seen by himself some time before which had been diagnosed by many physicians to be one of neurasthenia. Dr. Gibson had concurred in the diagnosis, but stated to the patient his fear that he would have locomotor ataxia. The subsequent history, although the patient passed from under Dr. Gibson's care, pointed to a confirmation of this diagnosis.

The paper was further discussed by Dr. H. F. Pitcher of Haverhill, and the discussion was closed by Dr. Bishop.

The Uses of Static Electricity in the Treatment of Gastric Disorders.—Dr. George D. Bond of Hillsboro, Texas, said that he had been able to get satisfactory results in the treatment of dyspeptic conditions from the use of a current which might be called a Leyden jar Morton wave current. The connections were the same as in the Morton wave, except that the wire connecting the patient with the machine was attached to the outside of a large Leyden jar, the patient being seated upon the insulated platform. The general electrification, though not so evident as in the current taken from the prime conductor, had an increase of volume and potential. There was contraction and relaxation of the stomach with each charge and discharge and in both its entrance and exit life and energy seemed to be given to this organ. In the past three years Dr. Bond had treated thirty-five cases of stomach disorder by static electricity with gratifying results. Several cases were cited.

Dr. Fred H. Morse thought the general practitioner was confronted with no disease conditions so frequently as those conditions complicated with dilatation of the stomach. He believed that in some of the various modalities of electricity there was a means of successfully treating many of the cases of chronic gastritis whether or not they were connected with dilatation.

Dr. Sinclair Tousey of New York City described his treatment of gastrointestinal disease.

Dr. Henry Finkelpearl of Pittsburg had used both the high frequency and the Morton wave currents and obtained better results from the Morton wave current than from the glass vacuum electrode.

Dr. J. H. Mudgett of Philadelphia called attention to the fact that the Morton wave current had not only a massage effect, but had an effect upon the organs which secreted the necessary juices for digestion.

Electricity in Joint Affections.—Dr. Henry W. Frauenthal of New York City restricted the scope of his paper to the use of the electrical armament in the diagnosis and therapy of affections in and about the joints. His own clinical experience was presented, with the work of other observers. In his results the *x*-ray had been of the greatest value in the determination of fractures extending into the joint, in subluxations, in malformations, in the presence of hypertrophic and atrophic bones at the point of articulation, in the various joint inflammations, and in conditions of the synovial sac and tendons of the joints. It was directed that an *x*-ray photograph of a joint should always be taken in two directions, the one at right angles to the other, and the distance of the tube specified. In tuberculous arthritis it was claimed that by the *x*-ray the points of tuberculous disintegration necrosis could be detected and the advisability of operative interference determined. A citation was given from the paper of Dr. John B. Murphy (*Journal of Advanced Therapeutics*, 1905), showing a great forward stride in the use of the *x*-ray in the treatment of tuberculous joints. In three cases of tuberculosis of the spine Dr. Murphy had had the most gratifying results, and the paraplegia often accompanying the condition had been manifestly improved. In the past five years Dr. Frauenthal had divided his cases of tuberculous arthritis of the spine, hip, knee, etc., into two divisions, each of equal severity, with the patients of the same relative natural resistance. In those treated by the *x*-ray, high frequency, and constant currents the time of treatment was reduced one-half, and pain was relieved almost immediately, while Nature's functions were stimulated into more rapid resolution. To these measures he had added in the past year the therapeutic measures of sunlight, diet, passive congestion (Biers), bodily exercise, mechanical protection of the joint, and psychical suggestion. In the consideration of gout and rheumatism Dr. Frauenthal described the special technique of the electrical treatment of the conditions. The increase of urea and of uric and phosphoric acids found in the urine after a few days' application of the high frequency currents was found to be very marked. The author did not advocate the use of electricity to the exclusion of medical means, but believed it to be a valuable additional therapeutic measure. For the prompt relief of pain he considered it to have no rival.

The Treatment of Lumbago and Other Painful Conditions of the Muscles of the Back.—Dr. Thomas W. Brockbank of Philadelphia regarded this condition more in the light of a local manifestation of a general systemic toxemia than as a special and distinct disease with a pathology peculiar to itself. The chronic and acute types were described with the mode of onset. In treatment the spinous processes were carefully observed as to perfect alignment. In the treatment of lumbago the physicotherapist was said to have modalities ranging from the hot domestic sad-iron to the static spark or the high power incandescent lamp. For the relief of pain the vibrator with ball attachment was used with at first light pressure and short strokes, followed by deeper pressure and longer strokes as tolerance was acquired. A few long indirect sparks were then given on the static platform. With nervous patients the Morton wave current was used, with a long electrode applied to the back. The importance of elimination through the bowels, kidneys, and skin was emphasized, and a few cases were reported in which the methods outlined had given satisfactory results.

The Present Status of Electrotherapy.—Dr. H. H. Roberts of Lexington, Ky., said that with all the advancements of theories, methods, and systems nothing had been received with more confidence and interest than electricity as a therapeutic agent. Although it had passed through periods of prominence and of depression, there had come enlightenment and confidence in electrotherapy. Because of the lack of uniformity in the manufacture of the various electrical apparatus comparisons in the work of operators was said to be difficult. The fear was expressed that the impetus given electrotherapy had caused the occupation of the electrical field by men totally ignorant of the science. Therapeutic results rather than psychological effects were desired by the honest and conservative

workers, and such workers should have a broad and comprehensive knowledge of electrophysics and electrophysiology. Since electrotherapy was a distinct science, the man who administered it should be as familiar with its effects and results as the man who administered medicine. The most essential requirement in the administration of electricity was said to be an adequate knowledge of physical diagnosis. Appreciation was expressed of the increasing realization in colleges of the importance of thorough training in electrotherapeutics.

Tuberculosis Antitoxin.—Dr. J. D. Gibson of Denver, in the treatment of tuberculosis, claimed that in suitable cases there was produced by the *x*-ray an autospecific or tuberculin toxemia arousing a reaction in the host of the liberated toxins which might be of great benefit to the patient. The cases best adapted to the *x*-ray were said to be those in which the germs were in sufficient quantity in the pleura, lungs, glands, or elsewhere to cause by their destruction the toxin desired. The value as adjuncts to the *x*-ray of rest, diet, sunshine, fresh air, change of climate, and medical agents was appreciated by the author. He pointed out the danger of exercise in high altitudes, which many thought was necessary in obtaining fresh air. Skiagraphic prints illustrative of the points claimed in the paper were shown. A number of cases were reported, in nearly all of which climatic and medicinal treatment was unsuccessful until combined with the *x*-ray.

Dr. Martin L. Barshinger of York, Pa., spoke of his highly satisfactory results with the high frequency current in pulmonary tuberculosis and exhibited two patients. The good results were attributed to improved metabolism and pulmonary circulation.

Dr. Frederic DeKraft of New York had controlled the temperature in advanced tuberculosis by the *x*-ray, using a tube with considerable penetration at some distance from the body.

Dr. Gibson in closing emphasized the want of necessity for the *x*-ray in incipient cases of tuberculosis. The fact of the greatest benefit being observed in the advanced cases was in marked contrast to the claims for other agents in the treatment of tuberculosis.

Rhythm the Dominant Factor in Therapeutics and in the Organic World.—Dr. Samuel S. Wallian of New York City in this paper said that the word "rhythmotherapy" was legitimately derived and comprehensively descriptive of a number of modern therapeutic expedients and of broad underlying principles which had hitherto been imperfectly and often inconsistently designated by other titles. Rhythm, he said, was the underlying law of the universe and life itself an incessant succession of rhythmic reiteration, while health was the uninterrupted play of the organ without jar or undue friction. Were rhythm, the underlying principle dominating every manifestation of Nature, eliminated, the entire curriculum of science would have to be reconstructed. Vibration was defined as the voice of Nature, without which she would be a helpless mass of immaterial matter, with no attributes of either cohesion or persistency. Physiology was said to be functional harmony; pathology, functional discord. Essentially then, in the attempt to change pathological into physiological action, there was the effort to establish lost rhythm in an arhythmic organism. That overenthusiasts had failed with the *x*-ray, with high frequency currents, with static modalities, and with mechanical vibratory manipulations, was not to be accepted as competent evidence against the intelligent employment of any of these rational measures. The enterprising practitioner, it was suggested, would study the nature, scope, and possibilities of such potent resources of an art which was yet in the swaddling-clothes stage of its ultimate growth.

The Measurement of the Intensity of the Roentgen Ray, an Element of Safety in Radiography and Uniformity in Therapeutics.—Dr. Sinclair Tousey of New York City said that the quality of the *x*-ray could be determined by measuring the penetrating quality of the ray by the Walter skiameter, depending upon the thickness of the platinum which its ray would penetrate. In the author's radiometer 1 to 10 thicknesses of tinfoil weighing one ounce to 100 square inches were used. Both of these were said to be dependent not only upon the quality, but also upon the intensity of the ray and the acuteness of vision of the observer. Other qualitative measurements were described. The author's method of quantitative measurement measured the intensity of the radiance by finding at what distance one could stand holding a fluoroscope to his eyes and see any trace of fluorescence when the current was turned on. If the radiance would carry six yards, the intensity was said to be six Tousey. If one could stand at a distance of twelve yards, the intensity was called twelve Tousey, and in that case the duration of application should be only one-quarter as long. An intensity of six Tousey with a penetration of three to eight Benoit would permit an extreme duration of application (at one time or in a series occupying a month) would be thirty-four minutes at a distance of six inches. The time might be increased if the intensity were less or if the distance from the tube to the patient were increased.

Dr. William T. Bishop thought Dr. Tousey had brought the matter of measurement to an approximately practical demonstration.

Dr. Tousey in closing called attention to the necessity of keeping the screen covered with a sheet of glass over the fluorescent screen.

Electricity as a Factor in the Treatment of Certain Chronic Diseases of the Stomach.—Dr. Otto Juettner of Cincinnati in this paper claimed that the practice of physiotherapeutic methods in the treatment of chronic ailments had established the superlative importance of the alimentary canal, more especially the stomach, in connection with the etiology and treatment. He believed the stomach occupied a much more commanding causative position than the text-books would indicate. He called attention to the anatomical position of the stomach and its share in the metabolic machinery as causative factors in disorders. Passing over the therapeutic indications, he limited himself to a consideration of certain electrical modalities in the management of these cases. A primary induced current of moderate intensity he regarded as useful as a muscular tonic to the relaxed and weakened walls of the stomach. With the intelligent cooperation of the patient direct application might be made to the gastric mucosa. The technique of this application was described. In many bad cases of gastric dilatation the results had been surprisingly good. It was understood that the hydroelectric applications were not to be used in cases of cancer, ulcer, or acute inflammatory conditions of the stomach. The static modalities appeared to be of little service in the local treatment of the disorders, unless there were used currents of relatively high frequency, in the form of either the static-induced or the static-wave current. The author emphasized the fact that in the treatment of stomach disorders it must be remembered that electricity alone was insufficient, even in the local management of the affected organ, and that the general treatment of the patient was of the utmost importance. Electricity should be combined with epigastric massage. The importance of diet was considered, especially with reference to the weight and bulk of the food. He believed degenerative changes in the nervous system to be the result of primary etiological conditions that were artificial products inasmuch as they could be removed in their early stages by strict attention to the functions of the organs of nutrition. He could not believe that nature ever intended the existence of so-called idiopathic paralyses. In the treatment of the secondary effects of gastric affections the author had found the gen-

eral application of high frequency currents to have a most salutary effect on metabolism and indirectly on the assimilative power of the stomach. He gave these applications once daily for ten or fifteen minutes. As an eliminative agent the incandescent electric light bath was given two or three times a week. The importance of attention to the bowel function was also emphasized.

Methods of Procedure in the Use of High Frequency Currents.—Dr. Frederic DeKraft of New York City said that the modern static machine seemed to be particularly well adapted as a means of charging the Leyden jars of a resonator on account of its extremely high potential discharge. The currents of high frequency and high potential which could be obtained from such machine and resonator were enumerated as the D'Arsonval, Tesla, and Oudin currents. The three methods by which the D'Arsonval current could be utilized were given and the technique explained. The class of cases yielding the best results in the author's hands with the O'Arsonval current had been conditions due to faulty metabolism, improper living, excesses in food and drink, and insufficient exercise. In five cases of obesity a reduction of from eight to twenty-five pounds had been accomplished within two months. Cases of gonorrheal rheumatism were much benefited. Cases of pulmonary affections responded well. The Tesla current had not been largely used by the writer because of its lack of adaptability for the bipolar methods. The Oudin current was said to be possessed of penetrating properties to a high degree. The manner in which this could be demonstrated was described. The several methods in which the Oudin current could be used were given in detail. It was suggested that much of the therapeutic value of high frequency currents was due to the actinic property of its spark and spray discharge and to its power to produce chemical changes in the tissues, as evidenced by the very great increase of the solid constituents of the urine, by the increase of the excretion of CO_2, as well as the positive increase in heat production and increased activity of the sweat glands. The remedial effects of the high frequency currents were considered to be due, in infectious diseases, largely to their power to check the formation of toxins, improve nutrition, and (when used in not too great amperage) to strengthen the natural defences of the body.

Dr. Edward C. Titus of New York City thought the close attention to detail shown in the paper of Dr. DeKraft was worthy of great commendation and his treatment of the joint cases was regarded in the light of a revelation.

Dr. Barshinger had proved conclusively to his own mind, by experimentation, that the current of the high frequency modality did penetrate the tissues.

Dr. Titus called attention to the fact that it was not the high frequency currents, as commonly accepted, that produced the penetrating quality of the current, but currents of low frequency and high potential.

Dr. Donaldson personally thanked the author for enlightening him upon the matter of technique. In the use of the Tesla coil he had seen special benefit in cases of mild pleuritic adhesions with slight temperature and some cough.

Dr. DeKraft in closing stated that the question of penetration was largely one of method. The methods were explained whereby the effect was largely surface, and in which the current passed to the vital spot.

A Clinical Demonstration of Radiotherapeutic Results in Cancer.—Dr. William S. Newcomet exhibited several cases. One case of particular interest was a patient with large round-cell sarcoma of the neck. Two years previous the first operation had been done, when the growth promptly returned. The *x*-ray was used with benefit, but a second operation was necessary. In spite of the *x*-ray the growth recurred and grew until the methods of deep treatment were instituted. The patient has been receiving an average of one hour *x*-ray treatment almost very day and the tumor had been decreasing. Dr. Newcomet described his devised method of treating four patients at one time.

Electrochemical Sterilization as Applied to Malignant Diseases of the Orbital and Nasal Regions.—Dr. G. Oram Ring of Philadelphia directed attention to the value of electrochemical sterilization as one of the very valuable adjuncts in the treatment and inhibition of certain types of malignant disease of the nasal and orbital regions. He believed that the bloodless devitalization of a malignant neoplasm, with the possibility of carrying the sterilization with precision beyond the growth into a region where some latent cells might be present and finally into healthy tissue, was of immense importance. In the treatment of orbital sarcoma, he reminded his hearers that if the modern viewpoint were correct, that every primary malignant growth was at first purely local and further that recurrence was highly probable, then with proper dosage and exact technique a method that made possible the destruction without subsequent stimulation was entitled to an important place in methods of treatment. A case was cited indicating the possibilities for good in electrochemical sterilization of malignant nasal disease after failure of *x*-ray therapy. After prolonged *x*-ray treatment without benefit, cataphoric sterilization under ether was performed. Five minor treatments removed all trace of the disease.

Cataphoric Treatment of Cancer of the Face.—Dr. Samuel McClary, 3d, of Philadelphia, in presenting this paper, stated that when there was no lymphatic involvement cancer of the face was probably best treated by cataphoresis, because (1) only diseased tissue and a small amount of healthy tissue was destroyed; (2) the resulting scar was less conspicuous than by any other method, except possibly *x*-ray treatment; (3) the danger of implantation was eliminated. The technique of the operation was fully described with the after-treatment. In some cases in which the current was not well borne, the bipolar method was useful, in that it did not embarrass the heart or respiration. In connection with his paper Dr. McClary exhibited several patients showing the effects of the cataphoric treatment.

An informal symposium on *x*-ray burns was held, participated in by Drs. Sinclair Tousey, A. C. Geyser, Brockbank, Brinkmann, M. K. Kassabian, and others.

A Résumê of the Radiometric Dosage of the Roentgen Ray Therapy.—Dr. M. K. Kassabian, in presenting this paper, classified and described the various methods in vogue, emphasizing the advantages and disadvantages of each. The twenty-one methods were classified under the following five headings: (1) The measurement of the electric current; (2) the penetration method; (3) the physicochemical method; (4) the ionization method; (5) the photometric method. After elaborating upon each of the above Dr. Kassabian commented on the fact that at present there existed no practical standard or unit of dosage. He urged that the selection of a standard and an exact unit was fraught with much difficulty; although a committee on meters was actively engaged in the work. Every individual, he said, was an equation unto himself, and no one could deduce the amount of biological and physiological action of the rays by measurement of their chemical and physical properties. The unit, to be ideal, must be accurate, precise, and practical.

Dr. A. C. Geyser of New York spoke of the great technical value of Dr. Kassabian's paper. He felt that Dr. Kassabian was absolutely correct in his statements concerning the personal equation.

Dr. Morris W. Brinkmann thought he had never heard a paper with which he so heartily agreed nor one which exhibited such an earnest search for truth.

Experiences with Electric Light in the Treatment of

Various Diseases.—Dr. H. Finkelpearl of Pittsburg, in this paper, stated that elimination was the most ancient method of freeing the body of morbid matter, and that of all the physical agents for this purpose electric light was the remedy par excellence. He reported a few cases treated by light, among which were conditions of albuminuria, jaundice, an affection of the skin (diagnosed by two dermatologists as psoriasis, and as lichen ruber), syphilis, scabies, and neurasthenia. The good results were general in all the cases. The following conclusions were drawn: (1) Radiant heat is more penetrating and consequently drains the deeper tissues much better than any other form of heat; (2) patients who cannot stand a high temperature will perspire at a much lower temperature when electric light is the source of heat; (3) patients will tolerate a higher degree of a longer exposure to radiant heat than to any other form; (4) that it may be given with impunity to people having a weak heart, if the patient is watched; (5) as the head does not have to be included, various substances may be vaporized within, and caused to be absorbed by the open pores, avoiding the liability of irritating the respiratory organs. The paper brought out a very extended discussion.

Concentrated White Light.—Dr. F. Barrett of Westbrooke, Me., presented this paper.

High Frequency Currents in Ophthalmic Practice.—Dr. L. Webster Fox said that his work had been of an experimental character. The current used was obtained by charging the direct currents of relatively low tension into alternating currents of exceedingly great rapidity and high tension through a large Ruhmkorff inductor, Leyden jars, and Oudin resonator. The applications were made directly to the eyelids by a Wappler vacuum spiral tube and directly to the eyeball by specially devised vacuum eye electrodes, single and double. The conditions treated included blepharitis marginalis, granular lids, ulcers of the cornea, iritis, ophthalmoplegia interna, and many others. From his experience with amblyopia he believed that the high frequency current offered a curative measure much more simple and radical than the fusion method with the amblyoscope. His attention had been first called to the treatment in this condition by Dr. David H. Coover of Denver. Dr. Fox, in closing, quoted from Guilleminot, who stated in regard to electricity in general: "If the progress of science finally enables us to master this force, which is the very essence of life, and to subjugate it, as steam has been subjugated to the service of mankind, we shall have ready to our hands the most potent curative agent imagined to modify the volition and ameliorate the condition of living beings."

Dr. S. Lewis Ziegler expressed his conviction of the advantage of the constant current. He had used the high frequency current, but not with the greatest success.

Dr. William W. Eaton of Danvers spoke of the value of the constant current in his hands in conjunctivitis.

Dr. J. D. Gibson of Denver was glad that the influence of Dr. Coover's work had spread so far from home and spoke of the enthusiasm he had aroused in Denver by his work with the high frequency current.

Fluid Extract of Sheep's Thyroid an Aid in the Treatment of Cancer.—Dr. Charles Am Ende of New York had used thyroid extract in the treatment of a number of cases microscopically ascertained to be malignant, and, with the exception of one, all inoperable. He asserted that the extract could be given in large doses for a long time because it was free of the substance of the crude gland productive of congestive and cardiac disturbances. Among its effects were mentioned: Elimination of cancer toxins, probably as an antibody; gain in physical and mental strength, prolongation of life, and alleviation of pain.

Officers.—The following officers were elected: *President,* Dr. Morris Weil Brinkmann, New York; *First Vice-President,* Dr. J. D. Gibson, Denver; *Second Vice-President,* Dr. M. K. Kassabian, Philadelphia; *Secretary,* Dr. A. C. Geyser, New York; *Treasurer,* Dr. Richard Joseph Nunn, Savannah; *Executive Council,* Drs. Wm. Benham Snow, Fred H. Morse, and Francis B. Bishop.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 11, 1906.

Dr. Matthias Nicoll, Jr., in the Chair.

Demonstration of a New Gas-Ether Inhaler.—Dr. Victor C. Pedersen made this demonstration.

Report of a Case of Paralysis of the Abducens Nerve Following Influenza.—Dr. Anna S. Wilner presented this paper, which was read by Dr. Barry. The patient was nine years old when the ordinary signs and symptoms of influenza presented. A few days afterward pain in the ear was complained of and the ear discharged. Later there were sharp pains on the side of the head and an intermittent curve to the temperature which ranged from 99° to 102°. The two possible causes for the fever appeared to be defective drainage and malaria, the diagnosis leaning toward malaria, although the spleen was not enlarged. Quinine was given, without appreciable effect. Later the pain on the side of the head appeared now and then. Dr. McKernon was consulted, and it was thought wise to insure better drainage by enlarging the opening. Later the child appeared heavy and drowsy and unwilling, taking no interest in anything. The child was somewhat dizzy and had a staggering gait, and another consultant diagnosed cerebellar abscess and advised operation. He based his diagnosis on the suppuration in the ear, the headaches, stupor, and dizziness. With the eye on the affected side blindfolded the dizziness disappeared. The eye muscles were affected. It was recorded that the muscles most affected in influenza were the internal recti. In this patient there was a paralysis of the abducens nerve and a resulting internal or convergent squint. These nerves were sometimes infected by organisms or influenzal toxins, just as they were in diphtheria. The nerve disturbances in diphtheria were more constant; in influenza they were more erratic. Literature had not informed us whether the lesions were in the nuclei or in the axons leading therefrom. The abducens was not the only nerve affected in this case; there was also a slow and irregular pulse and a sleeplessness lasting twelve hours, probably due to the direct action of the microbes, and accompanied by high fever, an occurrence appearing as a rule earlier in the disease.

Dr. Alfred F. Hess believed that the symptoms presented by the child could have been caused by other organisms, while the heart symptoms could have been caused either by the pneumococcus or the diphtheria germ. He failed to see why the writer of the paper believed the condition to be due to influenza.

Report of a Case of Splenectomy for Splenomegaly in a Child Eight Years Old.—Dr. David Bovaird, Jr., reported this case. The child was born in England and lived there till seven weeks before her admission to the Presbyterian Hospital, May 8. There was no suggestion of specific disease in the family, and the other four children were sound. There was no history of rickets. She was never robust and was easily fatigued. When eighteen months old she had measles, which was followed by pneumonia. In August, 1905, she began to have a persistent cough, with occasional hemoptysis. Shortly afterward she was in the hospital with scarlet fever. There was no history of rheumatism, typhoid, or malaria. Since having scarlet fever she had frequent attacks of epistaxis and a persistent cough, and complained at times of abdominal pain, vague both in location and character, and which was at times fre-

quent and severe. Bleeding from the gums sometimes followed the coughing. On admission to the hospital the notable features were the easily bleeding gums, a liver which extended from the fourth rib in the midclavicular line to one inch below the free border of the ribs, a spleen which extended from the seventh space in the axillary line to the level of the anterior superior spine of the ilium below and on the right to a point two inches to the right of the umbilicus. There were also noted a few râles at both bases behind, and a slight degree of jaundice. During the seven weeks under observation the cough subsided and the general condition improved. There was a moderate degree of anemia, no leucocytosis, and a moderate increase in the lymphocytes in the differential count. The urine was normal. The condition was regarded as splenic anemia, belonging in the class of Banti's disease. After careful consideration the removal of the spleen was advised and performed June 28 by Dr. McCosh. A good recovery followed. The only notable change in the blood following the operation was the development of a leucocytosis of from 20,000 to 25,000 There was no marked change in the differential count. The spleen weighed almost two pounds and appeared normal, except for the presence of a broad, yellowish plaque just beneath the capsule on the external surface, and which proved to be a deposit of fat. The microscopical examination showed only a simple hyperplasia of the organ.

Dr. Henry Ewing Hale, Jr., said that he had seen a girl of seven or eight years with liver and spleen in practically the same condition as the one reported by Dr. Bovaird. The *x*-ray treatment was given without making any impression upon the size of the spleen. After each application of the *x*-ray, there was an increased leucocytic count. Operation was advised, but the patient went to another hospital and was lost sight of.

Report of a Case of Septic Endocarditis.—Dr. W. C. Gardner made this report. He said that septic endocarditis was, in the vast majority of cases, a secondary disease and occurred with pneumonia, rheumatism, gonorrhea, puerperal sepsis, scarlatina, smallpox, erysipelas, typhoid fever, measles, and probably other diseases. The morbid anatomy was that of a simple endocarditis, with the septic feature added. Septic emboli were common, occurring most frequently in the spleen and kidneys. The prognosis was so grave that it was said a recovery meant a mistaken diagnosis. Recoveries, however, had been reported. Certain reports showed that septic endocarditis should not be considered as hopeless, and a consideration of the variations that might occur in some of the chief factors of the disease led one to believe that there must be considerable variations in the results. The diagnosis was often extremely difficult, and at times impossible. Dr. Gardner then reported a case he had under his care, in which the antistreptococcus serum and unguentum Crède had been used, and recovery followed. He called attention to certain flaws in his case. The septicemia was not proven, as there was no culture made from the blood; the endocarditis was not proven, as the murmurs did not persist; and the septic endocarditis remained unproven because the patient did not die. This was the negative or theoretical side of the case. On the positive and practical side there was presented a desperately sick child with a septic temperature, a recently developed cardiac murmur, and a markedly tender spleen.

Dr. Sidney Valentine Haas said that some years ago he saw an adult suffering from general septicemia, following wound infection, treated by antistreptococcus serum, with a prompt recovery. The patient was a woman, eighteen years old, who was operated on; following this she developed a pericarditis, endocarditis, meningitis, and pleuritis, and she was taken to the operating room to have an amputation done at the hip. The consulting surgeon advised sending her back to the ward, as he thought her to be in a dying state. The house surgeon suggested trying antistreptococcus serum; the attending surgeon was willing to try anything, and therefore the antistreptococcus serum was used. At the end of four days she was practically well, and in two weeks' time she left the hospital. Although she had all the classical signs of an acute septicemia, which usually ended fatally, she recovered under the use of the antistreptococcus serum.

Dr. L. E. La Fetra said that in all septic processes in the body one should realize that, varying with the virulence of the germ and the resistance of the patient, one got different types of the disease. Blood cultures were absolutely necessary, not alone for diagnostic purposes, but to guide one in the treatment of the case. Unless one could identify the particular type of streptococcus, and unless one could identify the various strains, and get a particular antistreptococcus serum for the strain, one must use a mixed antistreptococcus serum.

Dr. David Bovaird, Jr., thought the diagnosis was a reasonable one and the recovery of the patient did not nullify the diagnosis. In infective diseases one met with all grades of manifestations. The more one studied endocarditis the more clear it became that one could not safely draw a sharp line between simple endocarditis with fever and malignant endocarditis. He doubted whether the antistreptococcus serum had anything to do with the recovery of the patient; the more one used such a serum the more one lost confidence in it, and for the reason that one could not get a serum of a particular strain of streptococcus.

Dr. George D. Scott said that the investigations carried on at the Harvard Laboratory had shown that unguentum Crède and other silver preparations were mildly antibacterial in action.

Dr. W. C. Gardner said that he was not an advocate of the antistreptococcus serum in these cases, but reports had been received that appeared so favorable that he had decided to try it, not knowing what would do good. It really appeared that there was something inherent in particular sera which acted with brilliant results in some cases, but without any effect whatever in others.

SECTION ON MEDICINE

Stated Meeting, Held October 16, 1906.

Dr. Warren Coleman in the Chair.

Opsonic Index in Typhoid Fever.—Dr. Warren Coleman showed a chart from a case of typhoid fever in which the opsonic index was read every day in Bellevue Hospital. So far as the published accounts went, he said there were not many observations made upon this in typhoid fever. Wright had done much work along this line, but little had been published. The readings were made by students at Cornell University, under the supervision of Dr. Hastings, and might be considered as being accurate. The readings were made during convalescence and were continued during the relapse and showed very interesting variations.

A Note on the Treatment of Psudomembranous Colitis.—Dr. H. C. Carter made this clinical report. Pseudomembranous colitis meant a form of colitis characterized by the passage of large amounts of mucus, either in the form of casts, tubes, or ribbons, occurring in neurotic individuals, particularly in women. His experience with these cases showed that they were most trying to treat. The results of the treatment in the cases he wished to report were so satisfactory that he felt called upon to draw attention to it. The main point in this treatment was simply applying massage, a rotary kneading massage. The fingers should be placed over the caput coli and a kneading motion made along the line of the colon. The superficial structures were made to move on the deeper parts, thereby getting a mechanical pushing on of the material in the bowel and, at the same time, stimulating the coats of the intestine. He reported the following case : The patient

was a girl 17 years old, whom he treated for one year while she was in Massachusetts, because of her inability to come to New York City. She had always been constipated since childhood. Nine years ago she was supposed to have had appendicitis. In October, 1904, when he first heard of her, she gave a history of having for six months previous continual constipation, with mucus in her stools in the form of casts and tubes, some being from six to eight inches in length. She was placed on the ordinary treatment by diet, injections, etc., but without effect. Her nutrition was kept up by hydrotherapy and other measures. For one year she continued the same, and then she came to New York City one year ago. Her stomach was carefully examined and found to be all right. She never had a movement without the aid of enemas or purgatives. In November she was given massage every night, the treatment lasting fifteen minutes. On the 15th of December she reported that there was no more mucus in the stools and that her bowels moved regularly every day without the aid of laxatives or enemas. Her improvement was gradual but continuous. She still kept up the massage. The next case reported was almost precisely similar, although the amount of mucus passed was not so large. The occurrence of ribbons, casts of the bowels and mucus was not so marked. For one and a half years previous to last February she passed mucus continuously. There was no pain in either case. They had so-called mucous colic, but it was not characterized by colic. Two weeks after this massage was begun she had passages without the use of enemas or cathartics, and passed a very little mucus. She complained of a slight soreness over the appendix. The treatment he used he believed to be well worth a trial.

Comparative Action of Digitalis and Strophanthus.—A. HATCHER read this paper, the object of which was to suggest that in all probability strophanthus would never rival digitalis in this country. The disadvantages of digitalis were well known and required but little discussion. Strophanthus was not an ideal substitute for digitalis. Digitoxin had a greater tendency than strophanthus to produce cumulative effects. Strophanthus was more soluble in water. Strophanthin would cause no constriction of the coronary vessels. The strength of the infusion of digitalis depended upon the fineness of the powder in solution as well as upon the preparation and freshness of the leaves. The insolubility of digitoxin was against its use. Digitalin in large doses was rapidly excreted by the kidneys. In comparing strophanthin with digitalis he could find no reason why Americans should adopt the same therapeutics as Germany. He called attention to the experiments he had made with frogs, determining what dosage would produce systolic standstill in 100 gm. of frog. Accepting 6/10 of 1 c.c. as the fatal dose for 100 gm. frog, he injected a corresponding amount of different tinctures obtained from different drug stores into different frogs. The first symptoms were noticed, as a rule, in from ten to fifteen minutes, and the most powerful action produced death in twenty-nine minutes. He saw no reason why one should not get a fairly uniform result from tincture of strophanthus from the various drug stores.

Dr. GEORGE B. WALLACE said that Dr. Hatcher had referred to the variations in the strength of strophanthus in Germany; the results of experiments here showed the same variations in the American product, and the same held true regarding digitalis. In Germany it had been shown that one tincture might be 200 times as strong as another tincture. In considering the two drugs from a therapeutic standpoint, one might consider the differences in action they possess. Digitoxin had a marked constricting effect upon all the vessels of the body, whereas strophanthus did not have such an action, except upon the mesenteric vessels. In dilatation of the heart, where the arterial side of the circulation was engorged, digitalis was more effective than strophanthus, because the constriction of the vessels was beneficial. Where there was pulmonary obstruction with dilatation of the right heart the use of digitalis, causing constriction of the pulmonary vessels, was a disadvantage. It depended upon conditions whether one used digitalis or strophanthus. Again it was well known that when digitalis was given by the mouth no notable effect resulted for twenty-four hours. If strophanthus was given, on the other hand, good effects resulted in two or three hours. Therefore, in treating a case of sudden heart failure, it would be useless to give digitalis by the mouth, expecting to get quick and good results. Good preparations of digitalin produced an effect in one-half hour, its highest effect occurring in one hour, and therefore was the best agent in heart failure.

Dr. E. LIBMAN said that at the last congress in Germany Fraenkel had advised the internal use of strophanthin in cases of heart failure. Some time ago he saw a case of typhoid fever with a not very large hemorrhage and in which strophanthin was used hypodermatically. The patient sat up in bed eight minutes after, complained of a constriction about the heart, and dropped over dead. In looking over the literature he found that strophanthin had an effect twelve times stronger when given hypodermatically than when given by mouth. Intravenously it was seventeen times as strong. Therefore, when administered hypodermatically, the dose should not be more than one-half to one minim.

Dr. H. P. LOOMIS said that strophanthus was used comparatively little to-day compared to its use ten or fifteen years ago. Strophanthus was one of the most unreliable drugs we had; it came from the interior of Africa and oftentimes was inert. The uncertainty of its preparations accounted no doubt for some of its noneffects. This drug would never take the place of digitalis. At the same time the use of strophanthus in children under twelve years with cardiac disease gave good results; children seemed to respond better to strophanthus than to digitalis. The Board of Health had reported that of the various samples of strophanthus obtained at the various drug stores in this city something like 60 per cent. were more or less inert.

Dr. MORRIS MANGES asked if it was a very common thing to find combinations of digitalis and strophanthus.

Dr. HATCHER replied that he had been a pharmacologist for ten years, and had never met with such combinations.

Dr. MANGES said that if there was one thing he thought to be common it was the combining of the various cardiac drugs, just as the combining of the various hypnotics, and he called attention to the paper published by T. Lauder Brunton years ago on this subject when it was a common practice. Dr. Manges had been doing this for years. When in Edinburgh a few years ago he went through Fraser's ward, where there were cases of badly compensated hearts, and on asking how much digitalis was given these cases he was told that they used only strophanthus in Fraser's wards; whereas in the other wards of the infirmary digitalis was preferred. He was amused to hear mentioned the prompt action of digitalis; if one wished a prompt action in cases of heart failure the intravenous injection of certain drugs, as camphor, should be used to keep things going until one got the slower effect from digitalis.

Dr. HENRY W. BERG said that many hearts would get along well simply with rest, as in Fraser's ward. Dr. Berg had never given strophanthus when he wanted to regulate the cardiac action. The only time to use it was after one had obtained all the effects from digitalis possible; then he stopped digitalis and gave strophanthus. In New York he did not believe one should cease using digitalis and substitute strophanthus.

Dr. THEODORE JANEWAY believed digitalis to be the mainstay in cardiac therapeutics, but certain fundamentals should be borne in mind. It was dangerous to place too much reliance on animal experimentation; the normal animal heart, in experiments, did not act precisely in the same manner as

the human heart. When he went on duty at St. Luke's Hospital he found all the cardiacs in the ward were being treated by digitalis, strophanthus and various other agents; there was not a case that had improved in one month. He continued the use of digitalis and strophanthus for one month and saw no improvement. He then obtained some English leaves that were known to be good; an infusion was made, administered, and within forty-eight hours all but one patient had a marked diuresis and slowed heart's action. He emphasized the importance of obtaining good English leaves to make the infusion. The fault with digitalis was not with the digitalis but with the pharmacologist.

Dr. HATCHER said he was not the champion of the indiscriminate use of digitalis. Strength of different preparations differed widely, and that prepared in July showed in some cases a variation of 400 per cent. with that prepared in September. If one asked for Allen's or English digitalis the pharmacist would dispense it.

The Bacteriology of Gonococcus Infections.—Dr. T. FLOURNOY contributed this paper. He confined his remarks to the purely bacteriological aspect of infections with gonococcus and also considered the statements of many observers who reported the finding of gonococci in comparatively unusual situations. The gonococcus was a flattened or biscuit-shaped diplococcus which did not retain the gentian violet of Gram's stain and did not grow outside the body except when supplied with certain media. For the definite diagnosis of the presence of gonococcus, cultural methods must be employed. The diagnosis of gonococcus infections in situations remote from the urogenital tract was more difficult than generally supposed. In cases of joint affection complicating urethritis and clinically accepted as gonorrheal in origin, there have been obtained from the affected joint diplococci which could not be regarded as gonococcus if one accepted the classical requirements for the identification of that species. During the past year at Bellevue Hospital a considerable number of cases of the various types had been studied bacteriologically. The first class of cases was a series of affections of the joints following urethritis. Of these it might be said that, while morphologically identical with gonococcus, all of the species of microorganisms isolated grew upon so-called plain media, and were accepted as unclassified types, with the exception of one strain which agreed with all tests for meningococcus. In order to secure further data for the comparison of these species, cultures were made from cases of acute gonorrhea in the wards and a fairly large number of strains of Gram-decolorizing diplococci were obtained. About 50 per cent. of these strains grew well on glycerin-agar in early and subsequent generations. From the facts given, two possibilities might be offered in conclusion. Either there might be present, in urethritis, besides the gonococcus, another more easily cultivated similar diplococcus, or the gonococcus, contrary to the accepted belief, was capable of growth on other than the serum media. What was true of urethritis was true of its complications, since it would be hardly tenable that the same microorganism could vary its biological characteristics with its change of locality in the body. He believed the clinician could safely make the diagnosis of gonorrhea in acute cases upon the evidence of Gram-stained smears alone. The bacteriologist could not accurately identify the gonococcus in the light of our present knowledge of its characteristics. He could, however, with certainty, identify the meningococcus, whatever its source; and he could differentiate further certain other similar diplococci which were classed as micrococcus catarrhalis.

Drs. Charles Norris, E. Libman, Robert T. Wilson, and B. Lapowski discussed the paper.

Gonococcus Endocarditis, with Report of a Case and Exhibition of Specimens.—Dr. MORRIS MANGES reported the case of a woman twenty-five years old who was admitted to his service at Mt. Sinai Hospital last February. Her previous history was negative. Her husband had some venereal disease, the nature of which could not be ascertained. She had a copious vaginal discharge of one year's standing. She gave a history of having been ill with malarial fever of mild type. There was pain in her joints, especially in the left wrist joint. She occasionally had chills, sweats, and general malaise. Temperature was 103°. All he could find on admission was an axillary adenitis of old standing and a heart change. There was a moderate hypertrophy of the left ventricle, and a soft mitral regurgitant murmur. The examination was entirely negative except the characteristic gonorrheal left wrist joint, the condition of the heart, and the bloody discharge. Smears from the vagina, urethra and cervix were all negative as to the gonococci. She had rather a marked anemia, 50 per cent. hemoglobin and 17,000 leucocytes. There was an irregular temperature. On February 14, sixth day after admission, the blood examination was negative. The Bier treatment was given the wrist without appreciable effect except to cause discomfort. After ten days, with no change in her condition, a sudden change was ushered in with a severe chill, cramps, but without any noted change in the heart. Blood culture was negative. The wrist joint was not aspirated. Next a typhoid state developed and the cardiac murmur became louder. There was a marked dilatation of the heart and a rapid increase in the white cells from 17,000 to 42,000, and the patient died suddenly. The specimens obtained at autopsy were shown. On the mitral valve there was a large mass of vegetations, on the surface of which no organisms were found; but going deeper and getting a small quantity of pus in the interior, positive cultures of the gonococcus were obtained. Unfortunately no cultures were taken from the wrist, uterus or tubes. This case was of particular interest because of the condition of the mitral valve. Dr. Manges then reported a case that had been under the care of Dr. Berg. The patient was a man twenty-one years old, who nine days after a gonorrhea had severe chills, fever, and, three weeks later, nephritis. An endocarditis next occurred, and death. The blood cultures were negative. At autopsy there were found marked vegetations on the aortic valve in which the gonococci were demonstrated. Because of the mildness of the sepsis no one would have thought of ulcerative endocarditis. He emphasized the point that after a gonorrhea the endocarditis that ensued was the mildest of all forms of ulcerative endocarditis with which one had to deal, and one should be careful in assuming that every case of endocarditis occurring with or following a gonorrhea was gonorrheal in origin.

Dr. E. LIBMAN referred to the autopsy findings. In Dr. Berg's case there was a perforation of the valve due to the vegetations on and over it. In another case a man had an aortic lesion with cerebral symptoms. Here there was a destruction of the aortic valve and a purulent myositis. In another case, one of Dr. Manges's, there was found a remarkable condition, really an abscess of the valve; the mucopus contained the gonococci. He said there was a group of cases in which the gonorrheal infection set up a myocarditis with temperature.

Dr. HENRY W. BERG reported the case of a commercial traveler whom he had advised to go to the hospital. He had a septic temperature curve. On the third day he had a chill of moderate severity and the day following Dr. Libman made a blood culture which was negative. Ten days later another blood culture was made with negative findings. During the last days of his life he was in a semi-comatose condition. On the fourth or fifth day nothing was to be heard in the heart, although sought for every day. The day before death a murmur was noted at the apex, a loud blowing murmur. Thirty-six hours after the appearance of the murmur the patient died in convulsions. Among the curious features of this case was the negative blood findings.

Dr. THEODORE JANEWAY reported a case of gonorrheal

endocarditis with recovery. In 1898 he saw a man who had an attack of gonorrheal urethritis which was followed by a gonorrheal arthritis and later by malaria. There was leucocytosis and a systolic murmur over the precordium. The patient was sent to the hospital. He developed an intense septic fever, with chill, fever and sweat twice or three times a day. The temperature ran to 105° and 107°; this was followed by sweating and a drop of the temperature to normal with intense prostration. He also had a severe nephritis and pleurisy on both sides with effusion. There was a soft systolic murmur which gave place to a diastolic murmur with dilatation of the right ventricle. The condition ran its course in three months, and was followed by recovery. Blood cultures were negative during the entire course. There was a gonorrheal endocarditis with the involvement of the pulmonary valves.

Dr. B. Lapowski asked if the dry and ulcerative endocarditis could be distinguished.

Dr. Cohen said that Dr. Janeway's case might be considered a worthy one, but he did not think one should base a diagnosis simply on a cardiac murmur when the patient had gonorrhea. In Dr. Manges's case he thought possibly the application of the Bier treatment to the wrist might have been a causative factor of the endocarditis. After the application of the rubber bandage the endocardial condition occurred.

Dr. Manges, in closing the discussion, said that to distinguish between dry and ulcerative endocarditis was a difficult thing. Bacteriologists must give more positive results than they had in the past to insure better diagnoses of these conditions. A gonorrheal endocarditis, especially of the ulcerative type, offered a better prognosis, far better than that due to streptococci.

Philadelphia Pediatric Society.

At a stated meeting held October 9, Dr. J. E. Hume exhibited "A Case of Abscess of the Lung." The patient was a girl about nine years old, in whom the condition developed in the sequence of an attack of pneumonia. Dr. W. S. Moorhead reported "Two Cases of Acute Alcohol Poisoning in Boys Aged Four and Seven Years," and exhibited one of the patients. The children were brothers and gained access to some whisky in which the parents had been indulging. The exact amounts ingested could not be ascertained, although they were not thought to be large. The younger child remained stuporous for twelve hours or more and was soon restored to his usual health. The elder child, however, developed convulsions in addition, and at times his life was despaired of. Eventually, however, he also recovered in the course of a week. Dr. E. E. Graham presented "A Brief Résumé of the Work Done in the Section of Diseases of Children at the Boston Meeting of the American Medical Association, Held in June Last." Dr. Alfred Hand, Jr., made "A Report on the Papers Read Upon Diseases of Children at the Toronto Meeting of the British Medical Association, Held in August Last." Dr. J. H. McKee presented "A Report of the Papers Upon Diseases of Children Read at the Bedford Meeting of the Medical Society of the State of Pennsylvania in September Last." Dr. W. S. Newcomet described, with lantern demonstrations, "The Relations of the Mediastinal Lymph Glands to Disease and Their Value in Early Diagnosis."

Hemorrhoidal Dilatations of the rectal veins so high up as to render the use of the proctoscope necessary for their detection may, according to Goldmann, be the source of occult hemorrhages forming the basis of severe grades of anemia, and should always be looked for in cases of anemia of unknown origin.—*Zentralblatt für Chirurgie.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending November 3, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	387	176
Diphtheria	239	25
Measles	64	3
Scarlet Fever	73	5
Smallpox	—	—
Varicella	48	—
Typhoid Fever	99	24
Whooping Cough	41	5
Cerebrospinal Meningitis	6	11
Malarial Fever	...	...
Totals	957	249

Resection of the Spermatic Cord Without Castration, an Operation Complementary to the Radical Cure of Inguinal Hernia.—J. Morin, in a recent thesis, advocates this method in selected cases. He bases his thesis on six observations. As suitable cases, Morin cites hernias which are very large and which have weak walls. Cases of recurrence, also, with a large orifice, are considered suitable for this method. The testicle does not become necrotic after this proceeding, and both of these organs are left in place. Further, the operator, being relieved from all annoyance with the cord, is able to close the inguinal orifice completely and thus give to the patient every chance of a permanent recovery.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending November 2, 1906:

HEREDITARY CHOREA.*

BY CLARENCE KING, M.D.,

MACHIAS, N. Y.

PRESIDENT CATTARAUGUS COUNTY MEDICAL SOCIETY; FORMERLY ATTENDING PHYSICIAN TO THE CATTARAUGUS COUNTY ALMSHOUSE AND HOSPITAL.

THE disease to which the name "hereditary chorea" has been applied differs widely from the ordinary form of Sydenham and suggests an altogether different pathology. Discovered apparently in 1841 by Dr. C. O. Waters of Franklin, N. Y., it attracted but little attention for more than forty years and remains to-day a poorly understood, although well-recognized affection. Waters' description, as published by Professor Dunglison in his "Practice of Medicine," gave a lucid account of the salient features of the disease, to which little of importance has since been added. His cases were observed in the southeastern part of the State, where he stated it was somewhat common and known to the laity as "the magrums." The next paper on the subject appears to have been the graduation thesis of Dr. Charles R. Gorman, which was presented to the faculty of Jefferson Medical College some time previous to 1848. So far as we can learn, this paper was never published, our only knowledge of it being from Professor Dunglison's reference† to the original manuscript. In 1863 Dr. Irving W. Lyon published brief histories of three cases and stated he knew of others he could cite to show its hereditary nature. His cases were typical of the disease, two of them showing heredity through three generations, while the third family was known to have been afflicted for at least four generations. This last also included an illustration where the disease had skipped one generation in a collateral branch of the family to appear in the next, a circumstance which some writers, including myself, have stated did not occur. Apparently without knowledge of these reports Dr. George Huntington, in 1872, called attention to the disease, as seen by him upon eastern Long Island, and he has been considered by some as its real discoverer, his name being often given to the disease. But it is only within the last twenty or twenty-five years that the disease has been generally recognized by neurologists, and in still less time that an attempt has been made at careful study of its pathology.

That hereditary chorea is a rare disease no one will deny, many neurologists in all parts of the world never having seen a case, unless on exhibition as a curiosity. At present the number of cases reported in this country probably does not exceed one hundred and fifty or two hundred, in spite of the fact that it is here the disease has been longest known. The late Professor Gray attempted to show it was not an uncommon disease, and said he knew of a dozen towns where it was present. But if we recall the fact that Long Island seems to have been the original center from which by far the greater number of these choreic families have sprung, and that New York, Connecticut, New Jersey, and eastern Pennsylvania had furnished a large proportion of all cases reported to the time he made that statement, we need not be surprised that a distinguished New York consulting neurologist should have seen an unusual number of cases. Nor would it be strange, considering the long duration of the disease, if some at least of his cases had been seen and reported by others. As regards its frequency in comparison with Sydenham's chorea, the proportion must be largely in favor of the latter, although that is far from a common disease. Personally, I have seen more cases of the hereditary than of the ordinary form, but I regard my experience as unusual, four of my patients in two different families coming under observation during my service at our county hospital. Aside from the localities already mentioned, cases of chorea have been reported in Ohio, Illinois, Iowa, some of the Southern and extreme Western States and Canada, many of them being terminal dementia cases in insane asylums. In Europe the disease has been observed in Germany, in Austria, in France, and in England.

Of the etiology of the disease little is known beyond the very positive influence of heredity. So decided am I as to heredity being the great predominating, if not the only, factor in inducing the disease that I should consider a diagnosis of this form of chorea unjustifiable without a history of adult chorea in an ancestor, a brother or sister, or a child. Yet Bower has reported a case which presents nearly all the characteristics of the hereditary disease, but in which he says there was an entire absence of history of heredity. He does not, however, state the ages the parents or grandparents of his patient attained or the causes of their deaths. In 1889 I suggested that possibly all cases in this country might be traced to eastern Long Island, as that seemed to be a center around which many cases clustered. Recently Dr. Jelliffe of New York has attempted to find, if possible, a heredity in a common stock of all American cases reported and has succeeded, I understand, to an unlooked-for degree. But we must admit that Bower's first case in a full-blooded negro does not fully conform to our ideas of heredity from a single source, but proves the possibility of another distinct cause.

Several other factors have been given as exciting causes by one author,* as rheumatism, pregnancy, hysteria, the emotions, and other functional nervous diseases, but from the evidence at hand we must regard their influence as very slight. Age, undoubtedly, is a factor of some importance, by far the

*Bary, Nervous and Mental Diseases, N. W., 1893.

greater number developing between the thirtieth and the fiftieth year, but several cases have been reported as beginning much earlier. Most authors agree that sex is without influence, but Gray asserts that females are much more susceptible than males. The three families reported by me show thirteen males out of a total of seventeen known cases, and upon tallying up all the cases I can find in literature there appears a slight preponderance of males. Whether other diseases or conditions act as exciting causes in a person predisposed by heredity by inducing a state of lowered vitality or an unstable condition of the nervous centers is a question we cannot decide from present data.

Our knowledge of the pathology of the disease is still more unsatisfactory than its etiology. Numerous autopsies have been made by competent observers, but with the result that no constant lesion, either gross or microscopic, has been found. That it is something more than a neurosis its uniformly progressive nature and constant termination in death, as well as the utter uselessness of treatment, would imply. Again, if a neurosis it would be likely to occur more often in females and during the time of greatest sexual activity. And it would be difficult to explain why numerous cases have not originated *de novo* somewhere in the world without the constant necessity of family inheritance. But as yet few, if any, cases have been reported where the diagnosis is beyond dispute in which an immediate ancestor not farther removed than grandparent has not likewise had the disease, and it has been possible in nearly every instance to trace this heredity back as far as accurate history of the family could be obtained. But while the autopsy findings have not been uniform, and hence are, to a certain extent, unsatisfactory, they have, nevertheless, established the presence of an organic lesion in or near the motor centers, tending to unbalance the normal functional activity of those centers. As long ago as 1887 Huber* found pachymeningitis in one of his cases, while Macleod found a hematoma of the left hemisphere in one case and several tumors of the dura mater of the left side, implicating the first and second frontal convolution in another. In both his cases there were atheroma and thickening of the cerebral vessels, while the brain substance was unusually hard and congested. Phelps's case showed atrophy of the brain, especially of the anterior part, with serous accumulations under the dura and in the pia arachnoid; also a cystic formation in the right lateral ventricle. Rusk has recently reported an autopsy in which he found a "diminution in size of nervous elements generally, a shrinkage of the cells in the dorsal root ganglia, and a pigmentary degeneration of the neuroglia and of the white matter about the periphery of the cord." Spiller's examination of a well-marked case was less conclusive, the lesions found being very slight. Stier, in comparing his findings with those of other authors, makes the deduction that the disease is always due to an inherited asymmetry of the brain, which begins with a proliferation, either diffuse or circumscribed, of the neuroglia in the motor centers, but is most marked in the second and third cortical layers. At the same time the blood-vessels become diseased and a condition of degeneration of the ganglion cells is initiated which slowly progresses during the life of the patient. In Osler's case the arachnoid was turbid and separated from the pia by a serous exudate, the large arteries were stiff and thickened, and in places showed hyaline degeneration, and fatty changes were marked in specimens from the cortex. These and other reports appear to show that an organic lesion is always present but that its exact nature is variable, tending, however, to induce sclerotic or degenerative changes with moderate atrophy of the convolutions.

*Virchow's Archiv, Bd. CVIII, p. 267.

The clinical history of the disease shows definite characteristics at almost every stage, the variations being slight as compared with other chronic maladies. Beginning in a person about thirty-five or forty years of age, one of whose parents has been likewise affected, it first manifests itself by irregular twitchings of the muscles of the hands or face, which slowly increase in severity, in frequency, and in extent of distribution. These twitchings are at first controllable for a short time by an effort of the will, but that same effort augments their severity after they have passed beyond restraint. During sleep they cease entirely, while in repose they are somewhat less violent, the only author recording a different observation that I have seen being Mackay, in a French-Canadian family in Montreal. The movements differ materially from those of ordinary chorea or of tremor, in that they are irregular, are coarse in nature, and increase very slowly year by year. Beginning almost always in the hands and arms, they first manifest themselves by a restlessness or sudden movement of the part which at first may be thought to be due to nervousness or to habit. But as they slowly increase, the face, lower limbs, and body become successively involved, and finally, after some years, they reach a stage where speech becomes indistinct and broken, locomotion uncertain and attended by falls, mastication and deglutition difficult, and the use of the hands for coordinate and exact movements impossible.

Possibly an attempt to describe the character of the movements may not be without profit. In the face or hands a movement consists of a sudden and more or less violent contraction of a muscle or group of muscles which is momentary in time and followed by complete relaxation. This is succeeded almost immediately by an equally strong contraction in a distant muscle or group, or perhaps simultaneously in two or more widely separated parts, as, for instance, in the face and one hand, or in a hand and both hips. The movements attack the flexor muscles almost exclusively, are painless, and extend over a far greater range than those of ordinary chorea, differing also from athetosis in that the contractions begin and end suddenly and are not wavy or attended by rigidity. The movements in the hand may affect the fingers only, or, as is more characteristic, the whole hand may be flexed at the wrist and drawn strongly to the ulnar side. The movements of the arm in one patient of mine jerked the hand from the lap nearly to the face. In walking this same patient carried the feet far apart, and after taking a few steps in an awkward manner raised one foot unnaturally high and brought it down firmly on the ground. Then stopping suddenly and bending his body slightly forward, with hips pressed back, he raised himself on his toes, and while rocking from this position to the natural one went through many contortions of features and gesticulations. Regaining his balance he then threw his body forward, and after taking three or four quick steps would come to another sudden stop. In this way he got around considerably, although he fell quite often.

The movements of the face, when they are present, generally affect the muscles of the inferior and intermaxillary regions principally, so that the cor-

ner of the mouth is jerked downward and outward. This may occur on both sides, but if so, the contractions are much stronger on one side than the other and may give rise to a smacking sound of the lips, as in one case of mine. Next to the muscles of the mouth, probably the one most often affected is the frontalis, by which the eyebrows are raised and the forehead wrinkled, and after that the muscles which depress the lower jaw and open the mouth. But the muscles of the face are by no means always attacked to the same degree and may remain entirely free, as in a probable case I saw through the courtesy of Professor Krauss at the Erie County Hospital. This patient was a male about fifty years of age and presented many of the characteristic symptoms of the disease, but a family history could not be obtained, either to confirm or confute the diagnosis, as the records were silent on that point, and the patient himself was deaf and dumb.

The general health of the patient appears for years to be but little interfered with, barring accidental sickness, the appetite being good or ravenous, digestion normal, bowels regular or, perhaps, slightly constipated, sleep natural, and the menses often typical of health. There is no marked emaciation or evidence of circulatory or metabolic disturbance. The features assume a dull, listless expression, but the mind remains clear and free from disease until a late stage as a rule; but finally marked mental unsoundness develops, which generally takes the form of a slow, progressive dementia. Burr,* however, has observed a case in which marked symptoms of acute excitation developed with delusions of grandeur and motor weakness, which continued for two or three months and then disappeared, leaving only some minor delusions. Most authors have noted a suicidal tendency in their patients or a history of suicidal attempts in their ancestors, but it is a curious circumstance that most of these efforts at self-destruction have failed. These attempts have, for the greater part, occurred at a time when the mental change was first commencing and the patient could look forward to a detestable and hopeless existence. Later, the mind becomes so blunted as to make them oblivious to appearances or the niceties of society.

There is nothing to show that patients with hereditary chorea are more liable to other diseases than are those not so afflicted. Hysteria, neurasthenia, epilepsy, and other nervous diseases are rare, and if they do occur must be regarded as accidental complications and not as essential parts of the disease. Sleep, as a rule, is good. Neuralgia and headaches, at least of a severe form, are not common and my patients have all been very dull to the sensation of pain, bearing without complaint such minor operations as the extraction of teeth, the opening of abscesses, or the stitching of wounds. Even the pain of pleurisy and of fractured bone has been insignificant as compared with other patients; but I regret I have never had opportunity to observe the pains of labor in a patient with this disease.

As regards the sexual function, all observation goes to show it is but little interfered with in either sex until the disease has become quite far advanced. Several authors have spoken of the large families their patients have had, in some instances two or more children having been born to patients after they had become distinctly choreic. Menstruation may or may not occur, probably following the same laws which determine its presence or absence in other chronic or exhausting diseases. Respiratory and circulatory disorders do not occur with any more frequency than in other diseases, except that autopsies show, as already stated, degenerative or sclerotic changes are often found in the cerebral vessels. For that reason it is remarkable that cerebral hemorrhage is not a common cause of death, instead of a rare one, most deaths being due to exhaustion, the direct result of the disease.

The duration of hereditary chorea is generally about twenty or twenty-five years. A few cases have been reported which were more rapid in their course, but acute cases of a few weeks' or a few months' time are unknown. The diagnosis must be from Sydenham's chorea, athetosis, the ataxia of paresis, and of disseminated and combined sclerosis and from simple, chronic adult or senile chorea. Ordinarily the diagnosis is easy on account of the history of chorea in a parent or grandparent; in fact, the patient and his friends are watching with fear for the expected development of the disease. It is most apt to be mistaken for the simple chronic form of adult chorea, but it can generally be readily differentiated by its absence of known cause, as pregnancy, hysteria, or serious disease of the heart or blood-vessels, by its very slow onset and by its history of well-marked heredity.

The treatment of hereditary chorea marks a sad chapter in therapeutics. Nothing as yet has been found of permanent benefit, and our only success comes from treating intercurrent complications as they arise. Arsenic, hyoscine, galvanism, and prolonged rest have been tried, but without favorable results, and the only effect of bromides is to hasten mental decay. Not a single case of cure is known in literature, and I feel sure if such a happy result had been attained within the last quarter of a century at least it would have been put in print. Nor is it possible to even hold in check or abate the severity of the movements except for a brief time. Waters, however, reported that in one of his patients the movements ceased temporarily under the influence of all instrumental music except that from a common Jew's-harp; but no other author has made a like observation. I recall that when a boy I heard a traveling lecturer, who was afflicted with some disease of an ataxic nature, but whose movements were quieted for about an hour by a few soft tones from a church organ. What his disease was I did not know, but since arriving at maturity and learning something of nervous disorders I have reached the conclusion that his movements were neurotic, if not assumed for sympathy, and that they could not have been due to organic lesions in the brain.

Of course persons predisposed by inheritance or patients in the early stages of the disease should observe the rules of hygiene, have plenty of sleep and rest, avoid all causes of excitement, and attend to all the functions of the body as well as to any minor ailments, especially nervous, which may develop. And all persons in these families should be advised against marriage, at least until the chain of heredity has been broken for two or more generations.

MAN'S NATURAL PROTECTIVE AGENCIES AGAINST TUBERCULOSIS.*

BY SILVIO VON RUCK, M.D.,

ASHEVILLE, N. C.

OF the natural protective agencies of the body, the intact skin first suggests itself as an important one. The highly developed stratified squamous epithelium of the epidermis presents at once an effectual barrier to the penetration of bacteria and a further mechanical protection, viz., the constant exfoliation of the superficial epithelial layers, practically removes them.

While it is true that the permeability of the skin for the tubercle bacillus has been proven by animal experiments, it is questionable that the conditions incident to the experimental technique would often obtain in nature, and also the more delicate structure of the skin of the small experiment animals would permit of a more ready permeability than the denser and thicker integument of the human species. In the same sense the skin of men offers a relatively greater resistance to infection than that of women and children, a fact well exemplified in the greater frequency of lupus in females and especially in early childhood. Furthermore, the temperature of the skin does not favor the development of the tubercle bacillus and, if we accept the views of Hahn,[1] the deficiency of water in the superficial epithelial layers and the acid reaction of the sweat contribute to its protection.

*Read, by invitation, at the meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee, at Chattanooga, October 2, 3, and 4, 1906.

Against infection of the digestive tract a series of protective agencies may be recognized, varying in nature and relative efficiency with the differences in structure and function of its respective parts. Thus the oral cavity, inferior portion of the pharynx and esophagus are clothed with stratified pavement epithelium which is not easily permeable. Bacteria which gain entrance into the mouth are, like the food, quickly surrounded by mucus and saliva* which prevent their direct contact with the mucosa, and then are expectorated or swallowed.

The inferior portion of the pharynx, with its smooth surface and abundant secretion of mucus, together with the frequent passage downward of food and drink does not afford favorable conditions for the localization of bacilli.

Similar agencies serve to protect the mucosa of the esophagus, and when this organ becomes the seat of tuberculous disease, which is seldom, the infection, according to Cornet,[2] is usually from the outer side, as a result of suppuration of caseous tracheal and bronchial glands which have become adherent to its wall as the result of inflammatory processes.†

Whether the tonsils may be regarded as organs of defense is doubtful. The participation of these glands in tuberculous processes is remarkably frequent; indeed, autopsy findings in individuals who have died of advanced pulmonary phthisis show that histologic tubercles are present in them in almost all cases. On the contrary, in cases in which tuberculous lesions of the lungs are slight, obsolete or absent, the involvement of the tonsils is exceptional.

The position of the tonsils is such that in the act of swallowing, sputum or food containing bacteria is forced closely against them, particles of which readily enter and are retained in the numerous crypts and crevices of their surface. Hence when great numbers of bacilli are brought directly into contact, as by the sputum in advanced cases of phthisis, tonsillar infection is most certain to occur.

In further explanation of the exceeding frequency of tuberculosis of the tonsils, Dmochowski [3] even attributes to the crypts a sucking power by which under pressure of the constrictors in deglutition their secretion is first expelled and then particles of fluid or sputum are drawn in as the muscles relax and the crypts again expand.

Moreover, the tonsils are often the seat of catarrhal inflammation which injures the epithelium, and according to the investigations of Stoehr[4] in all mammalia possessed of tonsils there is normally a constant emigration of leucocytes from the adenoid tissue through the epithelium into the oral cavity. The leucocytes push through between the epithelial cells, compromising their function and even destroying it.

But how are these facts and phenomena to be

*Sanarelli claims to have shown a pronounced bactericidal action of the saliva (*Centralblatt für Bakteriologie*, Vol. 10), but in this he is not confirmed by the observation of others.

†Besides 19 cases which Flexner had previously collected from the literature, including one of his own, Cone (Johns Hopkins Hospital Bulletin No. 80, Nov., 1897), found 82 others, subsequently recorded. She, herself, added another, making in all 48 cases of esophageal tuberculosis reported up to 1897. Her study of the subject shows that only about one-half owed their origin to extension from adjacent parts. That tuberculosis of the esophagus occurs more frequently than these figures indicate, I am convinced by the fact that in my own notes, which are incomplete, I find references to 22 additional cases reported since 1897. In 12 of these only, was the mode of invasion that of which Cornet speaks as the usual one. To the 70 cases thus assembled, I am able to add still another of my personal observation in which a tuberculous abscess of one of the deep cervical glands communicated with the esophagus.

interpreted? Do they signify a peculiar disposition to infection of the tonsils, or are they by nature's intent so situated and so constituted as to bear the first brunt of invasion in this region of the body? In structure the tonsils correspond to the lymph glands which are known to arrest bacteria and to become themselves diseased while acting as barriers to the advance of infection to other parts. Reasoning upon this analogy Metchnikoff sees in them, and also in the lymphatic structures of the intestine, a defensive apparatus which produces phagocytes for the destruction of pathogenic microorganisms. In this belief he finds support in the work of Ribbert,[5] Bizzozero,[6] Manfredi,[7] and Ruffer,[8] who observed bacteria enclosed in the leucocytes of the tonsils, solitary follicles and Pyer's patches of the intestine.

In the gastrointestinal tract the constant peristaltic motion hinders the localization of tubercle bacilli which may be swallowed with sputum or ingested with food and carries them out with the feces.

Numerous investigators have sought for additional protective agencies in the digestive juices, but their experiments have led to contradictory results. Wesener[9] found that by neutralizing the gastric acidity of experiment animals with alkalies synchronously with the feeding of tuberculous material, infection of the intestines was more uniformly successful than when alkalies were not administered. London[10] was able to observe a bactericidal action of the gastric juice after it had been neutralized and which was not destroyed in all cases by heating for an hour at 55° C., and Strauss and Wurz[11] showed that the bactericidal action of the gastric juice runs parallel with its content of hydrochloric acid. On the other hand, Falk[12] subjected tuberculous material to artificial digestive influence and likewise experimented upon animals, finding that the digestive process does not destroy the virulence of the tubercle bacillus and observing infection to occur despite the action of the gastric juice. Ferrannini[13] showed that the gastric juice, taken from the human subject and kept at body temperature from one to two hours does not destroy tubercle bacilli, which nevertheless proved infectious for guinea pigs. Not without interest in this connection is a case reported by Curschmann[14] in which the pylorus was surrounded by a cicatricial tuberculous ulceration and in which free hydrochloric acid which was present in the stomach evidently failed to protect the patient. All in all the weight of experimental evidence, coupled with the fact that tubercle bacilli can be grown upon media which contain almost as much acid as the gastric juice, renders it highly improbable that the stomach possesses any bactericidal power over the tubercle bacillus, which is attributable to the acidity of its secretions. That its hydrochloric acid exercises some degree of inhibitory influence the experiments with alkalies are indicative.

Concerning pepsin, Miescher[15] has demonstrated that it exerts almost no digestive action on nucleins, and in view of this Hahn[16] thinks there is little likelihood that this ferment has an appreciable digestive influence upon the body substance of bacteria.

The study of the other secretions of the digestive tract and its tributary glands has likewise failed to reveal bactericidal effects upon the tubercle bacillus. Falk[17] for example, exposed tuberculous cavity contents to the successive actions of saliva, gastric juice, bile, pancreas extract and putrid bile and intestinal fluid. Only the putrid fluids proved active in destroying the tuberculous virus. Frank[18] found that the digestive juices have no power to destroy the tubercle bacillus. Hydrochloric acid 0.05 to 0.1 per cent. added to fluids containing the bacilli and allowed to act from one to six hours in the incubator, as also pepsin 1 to 1000 and bile 0.3 per cent., never prevented infection. Sergent[19] subjected tubercle bacilli to the bile without producing in them any changes in their staining properties, growth, or virulence. Cadéac and Bournay[20] fed dogs with tuberculous tissue and found large numbers of living tubercle bacilli in the feces. Intestinal digestion, therefore, did not destroy human tubercle bacilli.

Within recent years a ferment has been discovered in the succus entericus which Powloff has called enterokynase. Delezenne[21] has shown this substance to be a true ferment and that it is derived from the lymphatic apparatus and particularly from Peyer's plaques, which Metschnikoff says contain a large number of mononuclear ameboid cells. Delezenne also demonstrated the presence of enterokynase in leucocytes. It is probably identical with the enzyme or digestive substance, which according to Metschnikoff dissolves bacteria within these cells, and while there is no evidence that it exercises a bactericidal action upon the tubercle bacillus, that it may have an inhibiting influence is not beyond the bounds of speculation.

Like the tonsils the follicles of the gut are exceedingly prone to tuberculous infection, localization in the intestine occurring with greatest frequency in those regions most richly supplied with them. But intestinal tuberculosis is of comparatively rare occurrence except in cases of advanced phthisis in which large numbers of bacilli are swallowed with sputum in the course of, and especially toward the close of, the pulmonary disease, while at the same time there is a progressive reduction in functional vigor as portrayed in the diminished secretion of hydrochloric acid, and in the failing powers of both gastric and intestinal digestion. The emigration of, and phagocytic action ascribed to the leucocytes of the intestinal follicles has already been mentioned. Viewed in the light of possible protective agencies it is not inconceivable that these structures in the healthy organism may cope successfully with tubercle bacilli if they do not reach them in too great numbers as Metchnikoff would lead us to believe.

Finally the rich bacterial flora of the normal intestine and its lively chemical activity have been thought to hinder the development of pathogenic microorganisms. The studies of Macfayden, Nencki, and Sieber[22] have shown that the saphrophytes of the small intestine decompose chiefly the carbohydrates with the formation of ethyl alcohol, lactic, acetic and succinic acids; also that the acid chyme from the stomach does not become neutral, much less alkaline, until it reaches the ileocecal valve. Whether this acidity, or the alcohol, or both, would oppose the growth of the tubercle bacillus is merely a speculative consideration.

For prevention of infection of the respiratory tract the cleansing of the air in traversing the upper portions thereof first claims attention. These parts are admirably adapted to this purpose and the function of the nose especially in filtering the inspired air is practically perfect. As the air enters the nasal vestibules larger particles of dust carried by it are arrested by the vibrissae and the direction of the inspiratory current is such that the finer particles and bacteria are drawn immediately against and deposited upon the moist surface of the anterior portion of the septum.[23] Here the greater part remains adherent while further deposition occurs as the current continues on its way through the intricate and mucus coated nasal passages to the nasopharynx. At

this point the inspiratory blast is deflected at a sharp angle against the upper portion of the posterior wall of the pharynx[23] which again conditions the deposit of particles still in suspension. Thus in ordinary atmospheres the air reaches the larynx practically free from dust and microorganisms.

The situation of the nose at the proximal end of the respiratory tract and its function as a filtering apparatus render it the most exposed part. For these reasons, at first thought it would seem that it should become very frequently the seat of primary tuberculous infections, but the contrary is the case owing to protective agencies with which it is remarkably well supplied.

Upon the septum where deposit of germs occurs first the true skin extends for a considerable distance before the mucosa begins. The cells of the epidermis here offer a greater resistance than the epithelium of mucous membranes. In other situations and especially those which lie in the direct path of the main air current of inspiration the mucosa is equipped with ciliated epithelium, the vigorous action of which rapidly transports particles of dust and bacteria onward to the nasopharynx. Moreover, the nasal mucous membrane possesses an intensity of reflex irritability not exceeded even by that of the eye. Chemical and mechanical stimuli of very slight degree provoke most energetic reaction. The vessels become engorged, the nasal passages are narrowed and there is secreted a thin watery fluid, in part contributed by the lachrymal glands, which, added to the mucus normally present, bathes the membranes and washes away foreign particles, which are besides forcibly expelled by the powerful expiratory blast in blowing the nose and in sneezing.

A germicidal effect of the nasal mucus has been shown by some authors, Wurz and Lermoyez[24] finding that it killed anthrax bacilli in from two to four hours. To the tears a bactericidal action has also been ascribed, which if true should contribute likewise to the protection of the nasal mucous membranes.

On account of the direction of the air current from the nose and the deposit of dust in this situation, the nasopharynx is a favorable port of entry for tuberculous infection, the danger of which is increased by the corrugated irregular surface of the pharyngeal tonsil which affords opportunity for the retention of bacteria. The possibility of protection, due to the lymphatic tissue of this structure, as has been considered in connection with the faucial tonsils, is equally problematic, but protection against local infection is to be found in the free secretion of mucus and the ciliated epithelium of the respiratory portion of the pharynx, and also in the act of hawking and clearing the throat.

Despite its exposed position tuberculosis of Luschka's gland is not as frequent as might be imagined. Nevertheless, tubercle bacilli and histologic tubercles have been found in excised adenoid vegetations sufficiently often to demand caution in the selection of cases for their removal, because of the mobilization of the infecting material which may follow such operations.

The protective provisions of the upper air passages have been well proven by the experiments of Goebell.[25] Having found that when these are intact the lungs of animals are free from bacteria, he showed that after experimental tracheatomies the lower respiratory apparatus become regularly infected.

Mouth breathing predisposes to localization in the lungs, for the filtering action of the nose thereby falls out. Nevertheless, only a small part of the dust inhaled enters the trachea, Kayser having shown that most of it remains upon the tongue and soft palate. As the inspired air continues its way to the lungs, corpuscular elements which have not been removed above are deposited upon the moist surfaces of the larynx, trachea, and bronchi, the many divisions and angles of which greatly facilitate the cleansing process. These portions of the respiratory tract, with the exceptions of the vocal cords and posterior laryngeal wall are also lined with epithelium of the ciliary variety, and which extends according to Landois to the distance where the bronchioles are only one millimeter in diameter.

For the function of the ciliary epithelium a fluid medium is necessary and this is supplied by the film of mucus which is everywhere present in the respiratory tract and which also shields the membranes from the penetration of bacteria. Furthermore, Kraft[26] has shown that the ciliated cells are themselves mechanically irritable and that dust excites their activity. Through investigations of the air ducts of warm-blooded animals he found that when catarrhal inflammation existed and the living membranes were heavily coated with thick mucus, the cilia were sluggish, the wave of irritation traveled slowly and was far more susceptible to all sorts of chemical influences than in the presence of the normal mucus secretions.

According to Englemann,[27] the rapidity with which the ciliated epithelium may move forward the fluid layer upon its surface is one millimeter per second, and Werner[28] estimates that it would take an hour to transport substances from the smallest bronchi to the larynx at the rate of one-tenth millimeter per second.

Last but not least of the protective agencies of the respiratory apparatus is the highly sensitive mechanism of the trachea and bronchi, the irritation of which by foreign substances Nothnagel[29] has shown to induce reflex cough. By this arrangement a powerful auxiliary is brought to the aid of the ciliated epithelium in the expulsion of dust and bacteria from the lower air passages.

Turning now to the genitourinary system, the bladder, as shown by Leube,[30] is, under ordinary conditions, sterile. This can not be due to the acidity of the urine alone for, as Hahn[31] remarks, in animals with ammonical urine the bladder also remains free from bacteria. The true explanation of these facts presumably lies in the frequent washing out by the urine and this also serves to protect the urethra. Against penetration of bacteria the epithelium of the vesical mucosa is relatively resistant, since it is of the squamous transitional type which is likewise common to the renal pelvis and the prostatic portion of the male urethra. Here this type gradually gives place to the columnar variety which continues to the fossa navicularis. This mechanically more favorable situation for the settlement of bacteria is again better protected by stratified pavement cells which constitute the least permeable form of epithelium.

The female urethra is lined throughout by this variety, while, moreover, its straighter course and shorter length renders it less liable to infection than its analogue in the male.

The vagina is similarly supplied with a thick layer of squamous epithelium, and experimental evidence indicates that its acid secretion is not an indifferent factor in its protection. Kroenig[32] found this secretion germicidal, pathogenic bacteria, and especially streptococci, being destroyed when introduced into the vaginæ of healthy women. Kroenig's observations are in accord with those of Menge,[33] who also

showed that the cervical mucus possesses like power. Additional confirmation of the bactericidal action of the secretions of the vagina is supplied by the investigations of Doederlein.[34] According to the latter this property is due to peculiar faculative bacteria, which he calls "vagina bacilli," and which he succeeded in culturing upon one per cent. sugar bouillon, to which was added a drop of vaginal secretion. Doederlein further ascertained that when the vaginal mucus is but feebly acid or alkaline in reaction these bacteria are absent.

No discussion of the protective agencies of mucous membranes can be complete without at least reference to differences in their permeability incident to age. Upon this subject a voluminous literature has developed in recent years, the preponderating evidence of which shows undoubtedly that the mucosa, like the skin, of infants and children everywhere permits of the penetration of bacteria more readily than that of adults, a fact which Behring utilizes in his unique theory of infection.

The external protective agencies of the eye and ear now remain for our consideration.

In spite of its exposed position tuberculosis of the eye is comparatively a rare affection. So far as concerns infection from without, this is primarily explained by the sensitiveness of the organ for foreign bodies. Very minute particles of dust which come in contact with the cornea and conjunctiva (and according to Cornet, so small a thing as a bacillus, measuring one-thousandth of a millimeter), are sufficient to cause a copious secretion of tears and a pronounced activity of the lids. As the result of this high degree of reflex irritability, particles of dust and bacteria, which are not screened out by the cilia of the lids, are carried by the lacrymal secretion into the palpebral angles and washed away, at the inner canthus through the canals, lacrymal sac, and nasal duct into the nose, whence their further removal has already been described. Of the tears, moreover, a germicidal action has been claimed by Bernheim, but this Bach was unable to confirm and sees in them only a mechanical agency. That they have no such action upon the tubercle bacillus is borne out by the occurrence of tuberculosis of even the lacrymal sac, cases of which have been reported by Knapp,[35] Schiele,[36] and others.

Except in cases in which tuberculous infection of the middle ear occurs through the blood, the route is almost always through the eustachian tube. The mucosa of the latter is a continuation of that of the nasopharynx and the movement of the cilia of its epithelium is toward the pharynx, while a further barrier to infection is to be found in the narrowing of the tube at the junction of the bony and cartilaginous portions. Under ordinary conditions it is hardly conceivable that infectious material can reach the tympanum by way of the external auditory canal. The fine hairs within the external meatus, the nature of the lining membrane, which renders it resistant to the penetration of bacteria, and its coating of cerumen are here effective provisions for the prevention of localization from which extension to the tympanic structures might occur. Only when there are injuries of the wall of the external canal as are often caused by efforts to remove cerumen by means of unclean instruments is local infection liable to occur, and in this connection I may mention an instance of my own experience in which a phthisical woman produced such an infection of the anterior wall almost at the drum membrane by means of a hairpin.

From the preceding paragraphs, to which much more might be added in the elucidation of an interesting subject, it may be gathered that the human organism is indeed well supplied with a host of protective agencies, against tuberculosis. The efficiency of these numerous agencies, depending as it does upon their integrity, is not always of the same degree. Through impairment of their function or by its destruction the protection afforded is often temporarily or permanently lost. Thus given the opportunity for tuberculous infection with this or that avenue unguarded, the bacillus may enter and become localized in the tissues. That this happens far more frequently than clinical observations of tuberculosis would indicate is well known, autopsy findings in persons who have died from other causes having revealed healed or latent processes, according to different observers, in from 40 to 90 per cent. That such lesions have not led to active and progressive disease during the life of the individual is owing chiefly to internal provisions for defense which constitute the natural resistance of the organism, a subject which I may not discuss at this time.

Under ordinary conditions, however, of vigorous adult health and vitality it is perhaps not presumptuous to regard the natural and uninjured protective agencies as quite effectual, unless the elements of infection gain entrance in extraordinary numbers.

A PLEA FOR EARLY SURGICAL INTERFERENCE IN PELVIC INFECTIONS.*

By J. C. TAYLOR, M.D.,

NEW YORK.

LECTURER ON GYNECOLOGY AT THE NEW YORK POLYCLINIC; CLINICAL GYNECOLOGIST TO THE WOMAN'S HOSPITAL; MEMBER OF MEDICAL SOCIETY OF THE STATE OF NEW YORK; OF THE CLINICAL SOCIETY OF THE NEW YORK POLYCLINIC, OF THE WEST SIDE CLINICAL SOCIETY, AND OF THE WOMAN'S HOSPITAL ALUMNÆ SOCIETY.

It is my purpose to deal with acute conditions mainly, as I believe the best results are obtained by attacking inflammatory conditions early. A few years back it was common practice to sacrifice tubes and ovaries lest a future laparotomy be required; and this effort at thoroughness deprived women of the function of menstruation, which is so intimately interwoven into their mental and physical wellbeing. It is better to conserve these organs, even if elaborate and hazardous procedures must be adopted.

A more thorough knowledge of the pathology of inflammatory diseases of the female pelvis, as well as of the different microorganisms causing structural change in these organs, has enabled us to be more conservative, by acting quickly, without any special danger of mortality. I do not intend, however, to advocate conservatism of special organs so far that the constitutional condition of women is endangered. There is a broader conservatism which seeks to restore the health of the patient, even if special organs be sacrificed to attain this end. Sentiment also plays an important part, as some women prefer to suffer untold agony rather than sacrifice any of their special organs. Such sentiments are perfectly proper and should be given due weight.

It is to this end that I make my appeal for early surgical interference in the acute infectious diseases of the female organs. Conservative operations may sometimes fail; and if so, radical procedures may be adopted later without any added risk to the patient.

The principal infections with which we must deal are gonorrheal, streptococcic, staphylococcic, colon bacillus, tuberculous, syphilitic, and others unclassified. Gonorrhea may at times be confined to the vagina by proper treatment, but, unfortunately, in a large percentage of cases a gonorrheal infection crosses the barrier (internal os) to the lymphoid lining of the uterus, and by extension through the tubes may involve the ovary. Here its destruction of tissue often produces grave conditions. For many years it has been customary in large hospitals to treat patients suffering from gonorrheal inflammation of the tubes by hot antiseptic douches, tampons, and ice bags over the lower abdomen until the acuteness of the attack had somewhat subsided. The tubes and often the ovaries were then swollen and engorged to such an extent as to be designated tumors, and they were ablated *in toto*. Early incision and drainage, I contend, would often conserve these organs, to the great advantage of the woman, even if somewhat damaged. The conservative work attempted was mainly to let out free pus in the cul-de-sac when the operator was convinced by the bulging of the posterior fornix that purulent exudate was present in abundance. The gonococci, when active in the uterine cavity, destroy the superficial cells, and, working their way into the deeper layers, cause a great amount of purulent exudate, destruction of outer layers with edema, and infiltration of the deeper structures, accompanied by congestion.

Unfortunately, after gonorrhea has once started within the uterus, it invades by continuity of tissue the Fallopian tubes. The deeper layers of the uterus may become the seat of such an active inflammation that the walls of the surrounding vessels and the surrounding lymphatic structures are involved; the normal structures disappear, and the interior of the uterus becomes a suppurating surface. Later, sclerosis ensues, followed by shrinking of the organ. This is frequently the case in mixed infections. The greatest damage, however, is done in the tubes, where the tissue is thin between the mucous and peritoneal surfaces and the mucous surface is lined by delicate ciliated epithelial cells, a direct blood supply from branches of one of the main arterial trunks of the pelvis. The germ here, as in the uterus, destroys by contact the superficial cells. The delicate ciliated cells rapidly succumb. The germs readily enter the deeper structures with the formation of pus cells, edema, and profuse cellular proliferation. As they approach the peritoneal surface a local peritonitis is set up with peritoneal exudate (nature's way of limiting the disease). As the infection approaches the fimbriated extremity of the tube the fimbriæ fold into the lumen, a local peritonitis results, and the tube becomes closed by agglutination of peritoneal surfaces. The lumen of the uterine extremity, being small, is closed early in the inflammation, as a rule, by intercellular proliferation. When both extremities are closed, what is generally known as a gonorrheal pyosalpinx results. If it be a true gonorrheal inflammation the thickening of the walls is greater in proportion than the fluid exudate in the preformed sac made by closure of the extremities. When mixed with colon bacillus we may have a tube greatly distended with pus and often free pus in the cul-de-sac. Occasionally one meets with a mild form of inflammation, caused by germs low in activity, where the exudate is only serous, with a little admixture of pus, forming what is known as hydrosalpinx. The walls are not much thickened, and are capable of much distention. The increased weight of the tube frequently causes it to sink down into the pelvis and drag down the other organs with it. In severe cases the tissue is deeply congested and very friable, because of an abundance of newly formed cells, which later, if allowed to go on, forms a closed pus sac, from which the woman must constantly suffer constitutionally, from the poisonous absorption. The ovary may also become involved and the whole process form one conglomerate purulent focus, plastered down in the pelvis by peritoneal exudate.

Gonorrhea may spread by direct continuity out through the tube rapidly and attack the outer tunic of the ovary, causing here, as it is prone to do elsewhere, a great amount of cellular proliferation, with the resultant thickening of the capsule, rendering rupture of the Graafian follicles more

*Read before the Clinical Society of the New York Polyclinic Medical School and Hospital, March 7, 1906.

difficult and more painful. It may penetrate into the stroma of the organ, though the best authors have been unable to find gonococci in deep-seated ovarian abscesses. They are far more likely to form superficial inflammatory cysts, such as are seen beneath the outer coat of the tube, or cysts of the Graafian follicles, in which the thickening of the outer coat has prevented rupture. If, however, the infection becomes mixed, a tuboovarian abscess or a simple ovarian abscess may ensue.

Is it possible to prevent all this destruction of tissue which so often occasions the sufferer loss of her genital organs? I think it is, provided an early diagnosis of the extension of the disease into the tubes is made. Given a case of gonorrhea about the external parts, urinary, etc., and the glands of the cervix, certain symptoms should be carefully watched for—symptoms which indicate an extension into the tubes, viz., rise in pulse rate and temperature, though not at all necessarily a marked rise in either. The pulse seldom gets above 110 or the temperature above 103 degrees. Pain, which is fairly characteristic, is a better guide than either of the other two symptoms mentioned. It is at first spasmodic, radiating downward, and is due to the muscular contraction of the inflamed tube; later it becomes boring and constant because muscular spasm in the tube has ceased and the extension goes outward toward the peritoneal coat. Exudate forms between the intestines and omentum, lying close to the broad ligaments, interfering with peristalsis; bowel inactivity and tympanites result. On examination both sides of the pelvis are found to be tender to pressure, both externally on the lower abdominal wall and in the lateral fornices. Most likely the examiner will be unable to make out any mass, and it is all the more favorable to the patient if no mass be present, as its presence indicates a stage too late to accomplish the best results. Pain and muscular rigidity are sufficient evidence that the tubes are already involved. I think it unwise to carry the examination so far as to add trauma to an inflamed area. In appendicitis surgeons of to-day do not wait until they feel a mass in the right iliac fossa before they venture an abdominal incision, but, guided by certain significant symptoms (not so different from those described above, except as to locality), they at once open the belly and nip the destructive process in the bud, so to speak. Fortunately for the gynecologist, nature has afforded him a nonabsorptive drainage canal, through which he can go with impunity, and attack the inflammation above. Moreover, the pelvic peritoneum has a great resistant power.

Given the evidence from the symptoms of involvement of the tubes, and knowing from microscopical examination and otherwise that the lower canal was previously affected, to apply an ice-bag, give douches and narcotics, and wait until the acute symptoms subside, in anticipation perhaps of a future operation, is in contrast to surgical principles as taught to-day. One might as well recommend that a cellulitis or osteomyelitis of the extremities should be treated palliatively until an amputation is necessary.

Recently I operated on a case which demonstrated the evils of palliative treatment. The patient contracted gonorrhea about four months previously, and it quickly spread to the tubes. She was sent to one of the large hospitals in the city and for three weeks treated by various antiseptic douches and an ice-bag applied over the lower abdominal region. At the end of the third week she was allowed to get up and go home, supposedly cured. Later she came under the care of a physician who recognized the condition as a salpingitis. The left tube filled that side of the cul-de-sac and contained several ounces of pus. Scarcely any normal tissue was left in its walls, and it formed one large pus sac, which was removed. The right tube, not so seriously affected, was treated more conservatively. I venture to say that if this girl's tubes had been opened and drained during the onset of the disease she would have retained her organs, though somewhat damaged, been free from a local peritonitis, and happy, instead of being, at the age of 19, with part of her genital organs removed and with only the hope that the remainder may undergo sclerosis.

The operation is a very simple one, though it requires a thorough knowledge of the female pelvic anatomy and careful manipulation of special instruments. An incision is made on the posterior surface of the cervix, at the juncture of the vaginal and cervical mucous membrane. Care is taken to keep close to the cervix, where the fold is easily seen. Care should also be exercised to make the incision at this point. A pair of blunt-pointed scissors, curved on the flat, are best adapted for this purpose. An incision cut in the curve of the fornix is apt to have a painful scar resulting, as the nearer we approach the rectum the greater the sensory nerve supply. After incising the mucous membrane and retracting the divided edges, a small amount of loose alveolar tissue, most marked in women after menopause, is seen, which is easily divided. With the back of both forefingers together and the palmar surfaces looking laterally, the opening can be enlarged, the uterosacral ligaments being carried outward on the palmar surfaces of the fingers, and the intestines being carried out of the way by means of the Trendelenburg position and held there by abdominal pads. The tubes are easily brought into view by means of proper instruments for retraction. If this procedure is adopted in the very early stages, the tube will be found reddened, swollen, and with a tendency to sink down into the cul-de-sac. It should be grasped on the dorsal surface with a pair of modified Hunter's forceps and pulled down into the opening. Let us pause for a moment and consider the blood supply of the tube. It, like the ovary, except at its uterine extremity, is fed by small ascending branches from the ovarian artery, which enter the structure from the lower surface; consequently whatever incision is made should be on the opposite side.

Care being taken to keep the intestines well walled off by pads, the tube is incised along its outer two-thirds on the upper border, the contents evacuated, and the whole surface swabbed thoroughly with 5 per cent. iodoform gauze. At first there will be considerable tissue oozing, which gradually subsides, no main vessel having been cut. A small strip of iodoform gauze is placed on the raw surface, the other end protruding into the vagina. The first effect is to reduce the interstitial cellular infiltration, as it is a well-known fact that the gonococcus does not thrive well on exposed surfaces, its natural abode being in the deep recesses of compound racemose glands; secondly, it drains off all the exudate from the mucous surface of the tube. The uterine extremity, during the first period of attack, drains into the uterus, as the spasmodic contraction of

this portion tends to keep it open. As the deeper structures are merely muscular, they become infiltrated, edematous, and early undergo sclerosis, with resulting constriction as a sequence. Almost invariably a stricture is found from 1-2 to 3-4 of an inch from the uterine extremity in cases of pyosalpinx of long duration. The gauze can be removed with safety in from five to six days from the cul-de-sac, as the life of the gonococcus is very short except in racemose glands and closed sacs. We prevent by this method the formation of large pus sacs or deeply infiltrated tubal walls with subserous cysts and adhesions and probable ovaritis, the remote effect of which is to produce a mild toxemia, with oftentimes the production of kidney lesions. Again, it is well recognized that patients absorbing pus are prone to contract pulmonary tuberculosis in their depleted condition, as well as a localized infection of the tubercle bacilli in the former site of a gonorrheal invasion.

Why should we wait until a large abscess has formed or the walls have become so thickened as to form a tumor of such size that extirpation is the only method of relief, when it is possible to accomplish as early reduction of the inflammation with a partial restoration of tissue? Of course, we cannot hope for a normal tube as a result. I do not believe that any tube which has been the seat of a purulent gonorrheal disease is ever left patulous with the cilia capable of performing their function; but by an early operation it is possible to save the organs and allow the woman to menstruate, and to hope for motherhood, which instinct even the prostitute hates to abandon.

The old idea that to enter the peritoneal cavity in the presence of an acute inflammation was equivalent to inviting death, is not borne out by experience. Out of a series of nearly fifty cases operated on by the late Dr. Pryor, in which I assisted, and in those performed by myself, not a single one showed any tendency toward peritonitis. In fact, I have never seen a case of pure gonorrheal general peritonitis. Out of this series of cases, over 50 per cent. were cured: I mean by "cured" the tissues involved underwent sclerotic changes and no evil symptoms followed. This was especially true of women in the better walks of life, where time, care, good nursing, and general conditions favored the return of full strength before resumption of marital functions. The remainder either did not treat their condition seriously or immediately went back to their original source of infection, or some other, and were reinfected. Still others subjected themselves to traumas of all kinds, trauma of coitus, etc., which has a bad effect on a recently infected area.

In cases where the inflammation has been under palliative treatment for a long time and is seen late, presenting upon examination a large pus sac, conservatism cannot be adopted with any degree of success. The changes effected are already too great to hope for any marked degree of restoration. Some advise opening through the cul-de-sac and later removal of affected area, which is about all there is left to do, no matter which method is adopted. The same holds true of tubes with very much thickened walls, with perhaps a small amount of succulation, the whole mass with quite a large per cent. of ovary included surrounded and bound down by peritoneal exudate. Removal under such conditions I believe advisable in the interest of the future health of the individual, as conservatism is misapplied in trying to save something which is certain to deteriorate the patient's vitality. Space will not allow discussion of the various methods of removal. Vaginal versus abdominal route has been discussed often enough already. One point I would like to mention, however, and that is that it is very easy to remove the tubes through the vagina and leave the ovaries, if they are in good condition, without in any way affecting the arterial blood supply. This is done without the use of a ligature, by means of a modified Skene's electrocautery clamp. The tube having been freed and brought down into the opening in the cul-de-sac, the clamp is applied close to it, including the folds of the broad ligament and the vessels contained therein. It is applied progressively to the cornua of the uterus. The most practical degree of heat to obtain is about 180° F., and this is kept up from two to three minutes. One can judge by the appearance, however, when the procedure is complete, by watching closely the tissue on the side of the clamp. At the moment it blanches white the current should be turned off. The viscera above are easily protected by means of a pad wet in cool sterile water. This method has two advantages: first, it does away with the presence of ligature material in the purulent field; second, it sterilizes the field to a certain extent and devitalizes the nerve endings, thereby lessening postoperative pain. To know just when to turn off the current is the result of experience in using the instrument. If properly applied, it does not cause slough to any extent, but more of a cellular healing process. Anyone who has ever experimented with the instrument must have been thoroughly convinced of the efficiency of this method so far as hemostasis is concerned. It is difficult to rupture a bullock's artery with a powerful syringe at the point where the application has been made. This experiment I have tried many times. I have seen several vermiform appendices removed by applying this instrument to the base, with good success.

If one has to deal with a case in which the interior of the uterus is badly infected, involving the deep layers, with the tissue changes which must occur, as well as the tubes and ovaries hopelessly diseased, I cannot see what is to be gained by leaving any of the tissue. The tissue left cannot functionate, and it invariably produces morbidity in the patient. Ablation, in my opinion, of the pelvic organs in the interest of the woman's future health is the logical method. I am fully aware some advise leaving the cervix, or at least the vaginal portion. In the first place, it is the seat of chronic inflammation of its compound racemose glands; secondly, it is not a center of sensation, as its nerve supply is sparse and it contains no erectile tissue; thirdly, I have seen women who suffered for months from a diseased cervix which had been left; fourthly, three cases of cancer have come under my observation at this site after removal of the rest of the pelvic contents. I have never been able to see why we should leave a diseased uterus after removing both ovaries and tubes.

We will pass now from an infection which spreads by continuity with tendency to become localized in the pelvis (though we sometimes have to deal with gonorrheal rheumatism and endocarditis) to one which rapidly spreads through the lymphatics and blood-vessels, producing general peritonitis. The one is feared for its local tissue destruction and the resulting morbidity, the other for its rapid and frequent cause of death. The

subject of staphylococcic and streptococcic infection after abortion or labor has been often discussed, and I simply bring it up as an instance, to show that early surgical interference in the pelvis in such infections has been proven to be a success. In such cases one has to make a diagnosis early and act quickly, or the postmortem will reveal the mistake.

The symptoms depend mainly on two factors, viz., the individual resistance of the patient and the virulence of the infecting germ. If the germs are very active and tissue vitality low, the course of the disease will be very short, only a matter of hours, especially in cases after the second or third month of gestation. On the other hand, the more marked the lesions we find, the greater the evidence that nature is doing her best to combat the enemy. It can be confounded with only one other condition by any intelligent physician, and that is sapremia. The microscope comes to our aid in doubtful diagnosis, though there is a wide difference in the symptoms of the two conditions. A septic condition may follow a sapremic one and the symptoms of the one run into the other. In sapremia there is usually a profuse, foul-smelling discharge, dark and often clotted, while in sepsis we find a thin, scanty, watery discharge. The onset of sapremia is marked by a rapid rise in temperature, full, bounding pulse, not usually above 100, resembling the early stages of pneumonia. Sepsis, on the other hand, is not apt to produce high temperature, but the circulation suffers from the overwhelming effect of the toxemia. The pulse runs up to 110, 120, 130, 140, and higher, and is soon characterized by its feebleness. The pallor, pinched nostrils, and herpes labialis are quite in contrast with the flushed cheek of sapremia. The one woman strikes us at once as being very sick, and feels so; the other does not suffer much, except the discomfiture of a high temperature, and often wonders at the anxiety of her attendant. The microscope again comes to our relief in making the differentiation. In sepsis the blood shows a marked increase in leucocytes, except perhaps in the very worst cases, where nature has been overpowered in the very beginning; the lochia almost ceases or becomes only a little watery discharge. The infection, starting at some focus in the uterine mucosa, usually the placental site, spreads rapidly through the sinuses and lymphatic channels of the uterus outward into the broad ligaments. The walls of the uterus become soft and edematous. The broad ligaments thicken from the swollen lymphatics, which often contain septic thrombi. There will be a sero or serosanguinolent exudate into the cul-de-sac. If this exudate be pus, the prognosis is better. It is seldom sufficient to cause any marked bulging of the fornix. Oftentimes we find membranous patches in the vagina and on the cervix, which in appearance resemble a streptococcic tonsillitis. The lymphatics of the external genitalia connect with the chain above in the pelvis, as Dr. Cermault demonstrated, hence the care that should be taken to keep lacerated surfaces surgically clean. Examination occasions very little pain and does not reveal any tumefied mass in the early stages. The broad ligaments give to the examiner the impression of fullness. Quite in contrast to the local pain in acute gonorrheal salpingitis, patients suffer more from abdominal distention than anything.

The operative procedure differs from the one described in acute gonorrheal cases, as the pathology differs. After the uterus has been curetted and packed with iodoform gauze to drain the lymphatics beneath the mucous surface, the cul-de-sac is opened.

Owing to the fact that we have to deal with the whole of the broad ligaments and posterior surface of the uterus, and not with the mucous surface of tubes, simply opening the tubes would not be sufficient; and again, the serous surfaces of the tubes are first attacked. If operated upon early, the resolution which follows leaves a patulous functionating tube, proven by children born to women after this operation. The very fact that we find fluid in the cul-de-sac indicates that the surfaces are attempting to drain themselves. If we open the cul-de-sac and pack it properly, we assist nature in three different ways: (1) by affording drainage; (2) presence of local antiseptic, which is absorbed constitutionally, as shown in the urine; (3) isolation of the infected organs. Iodoform gauze, 5 per cent., recrystallized, acts best. The packing should be done by special instruments, in such a manner that the posterior surface of the uterus and broad ligaments are separated from the intestines, making a dam of gauze across the pelvis. If this procedure is carried out early it not only means a life-saving one, but insures quick resolution of the inflammatory process and a restoration to normal tissue.

Purposely I refrain from mentioning cases after childbirth which manifest malarial symptoms, and the diagnosis as well as the complications of pelvic sepsis, such as pneumonia, endocarditis, arthritis, multiple abscesses, etc. Time will not allow it.

One point I would like to lay stress upon, and that is, greater care should be taken to keep the emunctories active, especially the kidneys, which suffer from the toxins. Saline infusions and enemas should be employed vigorously to obviate this result. Patients with a low form of infection, who are constitutionally strong, put up a good fight, but the infection may work its way outward and produce multiple abscesses in the broad ligaments and perhaps in the ovaries. Simply opening the cul-de-sac and draining is toying with the condition. What is needed is wide dissection to the brim of the pelvis, thorough packing, and drainage. If the deep structure of the ovary contains an abscess, nothing avails but removal.

Again I ask, why should we allow the process to reach this stage?

In conclusion, the beneficial results of this treatment are obvious: there is practically no mortality, and its curative effects, if cases are operated upon sufficiently early, can be proven by the histories of one hundred of my cases.

32 West Thirty-sixth Street

Sprays of Ether and Chloride of Ethyl in the Treatment of Malignant Pustule and Lupus.—Gattone Vincenzo has tried the effect of sprays of ether and ethyl chloride on pagerms that have a low resistance to cold, with the view that the freezing, combined with the antiseptic effects of the drugs, will aid in the cure. He has made use of this treatment in two cases of lupus vulgaris and five of malignant pustule with ether, and two of the latter with chloride of ethyl. The results with malignant pustule were excellent. In advanced cases it is best to make two or three incisions before spraying the ether on. With moderate curettement of the ulcers it gives good results in lupus. The treatment produces a marked reaction in the tissues, congestion, afflux of leucocytes to the part, and increase in the nervous and vital energies of the cells. The method is easy of performance, not painful, rapid, and has good cosmetic results.—*Rivista Internazionale di Terapia Fisica.*

RESULTS IN ROENTGEN THERAPY.*

By CHARLES LESTER LEONARD, A.M., M.D.,

PHILADELPHIA.

Clinical results, as compared with other methods and agents, are the standard by which any new method or agent is finally judged. Each passes through a series of reports, pro and con, before it establishes itself by this final test. Many remedies have fallen far short of what was expected of them. Many have fallen altogether out of sight. As often happens in the early enthusiasm of a new discovery, hyperenthusiasm and a lack of scientific observation and judgment lead to extravagant claims. An agent like the Roentgen rays, at the same time mysterious and yet powerful in its action, tends to produce exaggeration and readily lends itself to the selfish exploitation of quacks and charlatans.

Much has been claimed and much attempted by those who had neither knowledge nor skill to apply this agent, or to appreciate the good results or failures it produced. Many reputable physicians have been beguiled into believing that they could produce good results, without giving the subject the necessary time and study, if they possessed a machine.

The failures resulting under such circumstances cannot be attributed to inefficiency in the agent or the method, and yet many of the failures to cure, what are demonstrated to be curable conditions, have been due to such causes. They are not reasons why this agent should be discredited or depreciated, or its study and employment abandoned by ethical practitioners.

It is undoubtedly a powerful therapeutic agent, which has its place in legitimate therapy and must be developed along scientific lines to attain its true value. It has only a place in therapeutics, and must be used in conjunction with other known remedies and methods to attain the best results, each being given that importance which experience in the conditions to be dealt with indicates.

There is possibly an optimism among Roentgenologists that lends credence to the supposition that they consider this remedy a panacea. Their willingness to attempt to relieve suffering or to try this new remedy in chronic and rebellious cases, would tend to indicate this. It has served to saddle the Roentgen method with the failures and mortality that belonged to inefficient agents and methods previously employed. There is a rational excuse for this optimism and readiness to try this new remedy in varied fields, and it is not as irrational as might at first appear. The Roentgen rays do not act through systemic absorption; they act in a purely local manner, stimulating the metabolism of the part treated and assisting nature to combat the disease by increasing the activity of normal cells, while decreasing the vitality of pathological tissues. Since this action is purely a stimulant and adjuvant to the natural processes of resistance and repair, it is difficult to limit the scope of its application. Roentgen therapy is therefore not to be charged with all the failures in cases where it has not been primarily employed. It would be very difficult to determine what percentage of these failures were due to inefficient Roentgen treatment, to the stage of the disease when submitted to treatment, or to the inefficient remedies or operations that had preceded it. The factor of inefficient Roentgen treatment is one that covers a large percentage of failures, and is difficult to deal with where so new a method is concerned. Reports that emanate from inexperienced operators receive as much credence as those of the expert, and the medical public has no way to differentiate the expert's opinion from that of the novice.

It is very important that the profession learn to judge and evaluate these reports, for not only is the Roentgen method injured thereby, but the safety of patients placed in inexperienced hands is also endangered.

The greater credence is always given to reports which chronicle failures. The scientific reporter is willing to report his failures as well as his successes. The ability rather than the veracity of a reporter should be questioned in a series of cases where his results fall far short of others of known veracity and standing.

In a method in which technique is so important and yet so difficult to attain, each success far outweighs many failures, because it shows that the method and agent, when properly employed, are capable of producing satisfactory results and that the failures are therefore due to defective technique or lack of knowledge in its employment. The results of Roentgen therapy must therefore be judged by the successes that have been attained in its employment.

As has been said above, it is of the utmost importance that the medical public learn to judge of the men competent to employ this great therapeutically if they would place their patients in safe and efficient hands for treatment. This method has been employed successfully for over a decade for diagnostic and therapeutic purposes, and there are those in every large community who have demonstrated by their results their ability to employ it with special accuracy and efficiency. It is no longer necessary to entrust its employment to inexperienced hospital residents or unqualified electricians and manufacturers.

Its use by such persons for diagnostic and therapeutic purposes has been shown to be not only inefficient and inaccurate, but often also very dangerous. This has recently been shown very conclusively by the work of Edsall who says of it "that it is undoubtedly the most violent known agent for therapeutic purposes and that this demonstrates, both great possibilities for good and great potentialities for harm." This warning, given out by Edsall, as the result of his investigations into the effect of this agent upon metabolism, has frequently been misquoted to mean that Roentgen ray applications are always dangerous and that more than ordinary care should be used in recommending or employing them. The danger he sees and is warning against is only in cases where the excretory and eliminating organs are pathological and incapable of caring for the products of increased metabolism resulting from effective Roentgen treatment. His observations have shown "that one exposure even may double the metabolic output in the next few hours; and, clearly, the necessity for metabolizing and excreting such an amount of destroyed tissue must be dangerous in a good many instances."

It undoubtedly would be dangerous in cases where the excretory organs are the seat of disease, and careful examinations for such defects should be made before referring any case for treatment and a report should be made of the findings. It is, however, of more importance

*Read by invitation before the Allegheny County Medical Society, at Pittsburg, October 16, 1906.

that the patient be referred to a Roentgenologist whose education and experience fit him to judge of the effects produced on metabolism and how to guard against and combat them.

Every Roentgenologist of experience has broken down masses of malignant disease that have necessarily been absorbed and has seen the effects of increased metabolism and the resulting toxic condition which will even put a patient to bed. He had recognized the danger long before the careful work of Edsall showed the increased metabolic output in the excreta. He had learned to employ this condition as a sign of efficient dosage, *i.e.* that pathological tissue was being destroyed and metabolism increased and as a warning that treatment must be suspended till the system recovered its equilibrium. The cases cited by Edsall are chiefly those of gouty and arthritic subjects, where the excretory and metabolic functions are commonly disordered. The increased stimulation of metabolism would undoubtedly throw a heavy load upon the kidneys with a possibility of an overload. Such conditions should be treated with the utmost care. An illustration of a favorable result in such a case occurred in the person of the wife of a prominent Philadelphia physician. She had been suffering for two years with a painful gouty and neuralgic condition of the jaws, with loosened and tender teeth precluding the use of solid food. Three mild treatments resulted in a uric acid crisis which put her in bed. When she recovered the tenderness in the teeth had almost entirely gone, and a few careful treatments sufficed to effect a cure.

The results in somewhat analogous conditions of neuralgia were reported by me at length before the Philadelphia Neurological Society. I was led to the employment of this method in neuralgias by the relief afforded from pain, in cases of malignant disease. My results since that time have been as successful, though not uniformly so. The reason for the variation in effect has not been determined, but may find its explanation in the causal factor, the neuralgias due to faulty metabolism being those to yield. Severe cases of tic, migraine, and persistent neuritis have been among those to yield so far permanent results for from one to three years.

The result in superficial lesions, the chronic and relapsing cases of skin disease, you have probably had demonstrated to you until you know where to send them for relief. The more you have this method employed in the earlier stages, the more you will appreciate it.

Of the results in the deeper seated lesions of malignant and glandular disease I wish to speak more at length. Particularly as the surgeons have recently demonstrated the efficiency of treatment in complaining of the increased difficulties which they find in operating after thorough Roentgen treatment. In a paper in the June issue of *American Medicine* I briefly discussed the findings and reports of cases made before the Philadelphia Academy of Surgery. It was there shown that it had been clinically demonstrated that the conclusions of Roentgen experimenters as to the degree of susceptibility of various structures was correct; that is, that the lymphadenoid or tissues of low vitality are first affected by the rays. All the clinical reports showed that in cases of tuberculous adenitis and malignant mammary disease, that had been treated by Roentgen rays previous to the operation, the lymphatic channels were found to be converted into solid cords, and furthermore that these cords rendered operation more difficult.

One result clearly demonstrated therefore of Roentgen treatment is the conversion of the lymphatic channels "into solid cords." This destruction of the lymphatics means the isolation of the foci of disease, the destruction of the paths through which metastasis or the spread of the disease could take place. What more can we ask than the localizing of disease whose danger lies in its spreading through lymphatic channels? What more forcible demonstration of results than those reported clinically and unanimously by surgeons? In the presence of such unsought testimony who can doubt the propriety of at least antioperative treatment by the Roentgen method, as a preparatory measure. If, as stated in the case then reported, twenty-eight treatments will convert the lymphatic channels into solid cords, should not every case be submitted to an effective course of such treatment before operation? The operation does not destroy the lymphatics, and in the vast majority of cases metastasis and recurrence follow operation. And we might further add if Roentgen treatment will destroy the channels for infection and localize the disease, what is the need for extensive operation?

Finally, the palliative value cannot be overlooked. Malignant disease too frequently comes for treatment too late, or incomplete operation results in recurrence. In fact, cures by whatever means are only too rare. The value of a method which certainly retards the progress of the disease, prevents external ulceration, and relieves pain is undoubted. To every patient suffering from inoperable malignant disease this agent offers a promise of palliation that cannot justly be ignored.

I have not attempted to enter into a detailed statement of cases and conditions in which results justify the value placed upon the Roentgen ray as a therapeutic agent. I have pointed out the facts that the good results only are a criterion of the efficiency of a new method and that they are to be compared with those obtained by other methods. That *a priori* we should expect such results as are obtained, because the rays have been shown to produce a marked increase, and even to double metabolic activity. That it is therefore one of the most powerful therapeutic agents that we possess and must be administered with caution and only by those educated and competent to observe its physiological action. I have pointed out the confirmation of experimental studies by clinical experience, demonstrating that this agent acts primarily upon the lymphatics, destroying them first and localizing the disease; preventing any spread or metastasis. This is a demonstration that makes it essential that every patient suffering from a disease which spreads by the lymphatics should be subjected to a series of anteoeprative treatments, if indeed operation eventually proves to be necessary.

I have finally pointed out the very valuable service which this agent renders as a palliative, and how it lengthens life and alleviates suffering in those malignant diseases in which the term cure seems justified only after the patient's death from some other cause and in which the actual mortality presents most convincing evidence of our scientific ignorance.

112 South Twentieth Street

REPORT OF A CASE OF CEREBROSPINAL FEVER.*

By W. O. WILKES, M.D.,

WACO, TEXAS.

J. G., aged ten, a healthy son of healthy parents, waked up February 14, 1906, about 4 A. M., complaining of "stomachache," and soon afterward vomited. His mother thought it indigestion and began giving him calomel. Soon after 5 o'clock he had a slight chill, followed by some fever and aching of his limbs and back. About 11 o'clock his father came to my office with this report, and asked for a prescription, and I gave him some euquinine in syrup of tolu. About 8 P. M. he telephoned me that the boy was vomiting occasionally and complaining of headache, the calomel was acting freely, and I told him to discontinue the euquinine, and sent some phenacetin powders for the headache. I heard no more from him until the next morning, when I went to see him and found him with a temperature of 100° and pulse 90, some headache and nausea. Still I thought it simply a case of grippe and gave some little powders for nausea and told him I would call again after dinner. At 2 P. M. I found a pulse of only 84 with a temperature of 102.5°, quite a disproportion, you see; the fever had gone up and the pulse had gone down. His abdomen was retracted, head somewhat drawn back, he was slightly delirious, and had a wild, pained look about the eyes, with slight incoordination of the eye muscles. All over his body and limbs there were numerous purplish brown spots from the size of a pinhead to the size of a pea, and a few much larger. Kernig's sign was very decided. That afternoon the patient was seen with me by several physicians, and the diagnosis was positive in the minds of each of us. At 8 o'clock his pulse was 80, temperature, 99.5°, some tendency to opisthotonos, and general hyperesthesia, and slight inequality of pupils, the right being contracted and the left about normal. He was given potassium iodide and ergot internally and enough morphine hypodermically to relieve the pain; icebags to the head and spine. A few doses of bromide and chloral were also administered to produce sleep. His pulse was very irregular, running at the rate of 120 for a few seconds and then dropping to only about 50 at other times, but averaging about 80 to the minute.

Third day, 8 A. M., pulse, 95, temperature, 100°; 2 P. M, pulse, 124, temperature, 101°; 8 P.M., pulse, 67, temperature, 100.5°. This slow pulse is considered a very unfavorable prognostic sign, and shows pressure. On this morning we did a lumbar puncture and drew out about an ounce and a half of turbid cerebrospinal fluid. After this the pressure symptoms were relieved, the pulse went up to about a normal ratio with the temperature, the pupils were alike, and the child slept for about two hours; then all the pressure symptoms gradually returned, and with increased intensity. The pulse dropped from 124 to 67 in a few hours; there was more opisthotonos, restlessness, jactitation, and irregular pulse. Bacteriological examinations of the spinal fluid showed the *Diplococcus intracellularis meningitidis* in abundance. A culture on blood serum developed them by the million in apparently pure culture. One specimen showed a diplococcus outside of a cell, and it was encapsulated—the *Diplococcus pneumoniæ*. This evening we dropped the iodide and injections of morphine and put him on bromide, gelsemium, and ergot, repeated every two hours.

*Read before McLennan County Medical Society, July 3, 1906.

Fourth day, 6 A. M., pulse, 124, temperature, 101°; 2 P. M., pulse, 90, temperature, 100.8°; 6 P. M., pulse, 90, temperature, 101°. The spots are beginning to fade. Icebags continued; hypodermics of morphine still needed occasionally. He is nourished with egg albumen and milk.

Fifth day, 7 A. M., pulse, 156, temperature, 102°; 9 A. M., pulse, 136, temperature, 101°; pulse very bad in character. We put him on fifteen drops of tincture of digitalis every two hours until it shall affect the pulse. He was also blistered over the spine; had the worst day and night since the beginning. In the afternoon his fever began to run high, 104° to 105°, necessitating frequent baths. His bowels have been acting every day, but he now has some difficulty in passing his water; it is diminished in quantity and passed only after much restlessness and great effort.

Sixth day: This morning an enema brought away a quantity of dark, soft, foul-smelling feces, besides a number of hard, dry scybalæ; his fever went down at once, and he slept quietly for several hours. Pulse from 116 to 128. The bromide and gelsemium have been continued, but at three to four hour intervals; digitalis the same. The eyes are much inflamed and the nose is discharging.

Seventh day: Fever troublesome again, 104° to 105°. Bowel irrigation, sponge baths, and ice water to head, keep it down only a small part of the time. Kidneys acting a little better. Nourishment, white of egg and milk punch, which he takes pretty well. Pulse from 130 to 140, and very bad in quality. The spots have disappeared.

Eighth day: Temperature about as yesterday, and pulse still weaker. The bromide, gelsemium, and digitalis were dropped and iodide and ergot substituted; hypodermics of morphine and strychnine were given at six-hour intervals, although strychnine is theoretically contraindicated in this disease. His pulse began to improve, however, and the strychnine has been continued at lengthening intervals. The rapid changes in his temperature are surprising; the desire to urinate, which is not quickly accomplished, will increase the fever one or two degrees, to go down again soon after it has been voided. Once his temperature was 104.5° and preparations were being made for a bath when his bowels acted; his temperature was taken again immediately, and it had dropped two degrees. There is considerable jactitation and the head is drawn far back.

Ninth day: He is better in every way; pulse, 120 to 130, temperature, 101° to 103°, and more easily reduced. Is a little more rational, complains very much of headache when not under morphine. Kidneys acting freely, food readily taken, panopepton added to diet. Eyes still inflamed.

Eleventh day: Pulse, 118 to 125; temperature, 101° to 103°. Milk has been dropped on account of fermentation and malted milk substituted.

Thirteenth day: Condition has been about the same for the last two days. Morphine and strychnine have been discontinued; nourished as before and icebags applied to head. Is more rational and fretful. Bowels have to be moved with castor oil. Iodide and bichloride were given, with the hope of hastening absorption of inflammatory products.

Sixteenth day: Condition not so good to-day; had a very restless night; cries and complains of headache all the time, and bromide was added to his medicine. Temperature 101° to 103° all the time. Pulse good, from 115 to 120. The amount of whiskey has been reduced from three ounces in the twenty-four hours to less than half an ounce.

Turns himself in bed for the first time and can lie on his back. Eyes still irritated.

Eighteenth day: Had a violent headache yesterday, requiring repeated hypodermics for its relief; continued for about twenty hours.

After this every two or three days he would have an agonizing headache for a few hours, necessitating large doses of morphine. I have given him three-fourths of a grain at a dose under the skin several times, and as much as two grains in a few hours. It seems to me that any attempt to give him either bromide or iodide increased both the frequency and severity of the headaches. With the exception of these headaches his convalescence was uneventful—except for one attack of heart weakness following acute indigestion about the fortieth day, when for two hours I thought he was gone. He was in bed for seventy days, and his return to a normal diet was very slow on account of weakened digestion. He had no sequelæ except a weakness of the eye muscles, which caused his eyes to tire very quickly and occasionally gave him an appearance of strabismus; his oculist assures him, however, that he will recover from that condition in a short time.

I do not know that this case will teach you anything, but it has me. I have arrived at some definite ideas regarding the treatment of this disease during the ten weeks that I studied it and the literature bearing upon it. These conclusions may not be well founded, but they are certainly deeply grounded, and, briefly stated, they are as follows: I do not believe that iodide, bromide, bichloride, or gelsemium have any beneficial effect whatever, and, in fact, I thought were harmful in this case. Ergot may have a limited usefulness, chiefly to aid the quieting effect of the morphine and as a heart stimulant. I believe blistering is worse than useless, and adds an element of irritation and pain, if not weakness, to a sufferer who already has a grievous burden of each to bear.

The chief indications are morphine hypodermically and icebags to the head and spine. Of course the beginning of treatment should be prefaced by a good calomel purge. Possibly small doses of chloral by the bowel or internally will help if the morphine does not produce sleep. Spinal punctures for diagnostic purposes and to relieve pressure symptoms I am sure are beneficial, and in another case, especially with parents in a different walk of life, I would do more of it. Nourish with albumen water and solutions of peptones; milk, if well borne; later use stimulants freely, as indicated, and I am not afraid of strychnine or alcohol in these cases if the heart seems to need support. The thing to do is to relieve pain, support the patient, relieve pressure if possible, and trust in the *vis medicatrix naturæ*.

The New York Department of Health quarantines meningitis for two weeks, the Waco Board of Health indefinitely. Now, my contention is that there is no more reason for quarantining cerebrospinal meningitis than pneumonia, erysipelas, influenza, or any other infectious disease. The evidence as to the contagiousness of pneumonia is immensely greater than that of meningitis, and the susceptibility of the human family to pneumonic infection is still greater.

Here was a case of great violence, shut up in a house for ten weeks with four adults and five children of varying ages, and no one else on the place showed any symptom of the disease. The fact that there were four or five other cases in the city at about the same time caused some uneasiness as to the possibility of contagion, but there was none traceable.

A cow on the premises was taken with "blind staggers" during the time and had to be killed, but its body was disposed of before an examination of its cerebrospinal system was thought of. If "blind staggers" is really meningitis, as is claimed, this was a valuable opportunity neglected, for some authorities believe that the infection of cerebrospinal meningitis is transmitted to man from domestic animals; but there is no evidence that it has ever been transmitted from man to animals. This cow's meninges certainly should have been examined in this case. Ia may have been merely a coincidence, but it looks as though this may have been an instance of transmission.

Typhoid and paratyphoid fever are dangerous diseases and communicable. Why not quarantine? Tuberculosis will attack anyone at almost any time. Dysentery is infectious; so are erysipelas and all streptococcic infections; puerperal fever is a terrible infection. Syphilis is extremely contagious. Gonorrhea causes probably as many deaths, and certainly a thousand times as much human suffering and unhappiness as meningitis; and here I will say that I believe that gonococci, pneumococci, and meningococci, and, in fact, all diplococci, are the same, differing sometimes in appearance, and often very much in behavior, according to the infinite variety of physical surroundings; environment, you may say. Heredity is a powerful force, but who is there who can say that environment is not still more powerful?

The origin and variation of species are going on about us all the time. It took centuries of weather conditions, environment, aided probably by artificial selection, to develop the shaggy Newfoundland and the hairless Mexican dog from the original wolflike domestic dog. It required many years of artificial selection to develop the fantail and pouter pigeons from the rock pigeon. Luther Burbank produces the most wonderful fruits and flowers in one or two seasons. The life cycle of low microorganisms may be only a few minutes or a few hours; why may they not undergo wonderful changes in appearance or behavior in a few days? The bacteriologist can, in the laboratory, increase or decrease the virulence of many of them at will; and I believe that environment can cause them to change and interchange characteristics, and possibly develop new forms in a short time. And then, too, we may have mixed infections. The supposedly harmless *Micrococcus catarrhalis* morphologically cannot be differentiated from the gonococcus or pneumococcus at times, differing from them only in its behavior toward culture media. Cases of meningitis have been reported in which the meningococci have looked so much like gonococci as to be indistinguishable. It seems to me a matter easy of belief that all diplococci, by whatever name they may be called, are of the same species, meningococci, pneumococci, gonoccoci, and all the others being only varieties, or, at most, very unstable subspecies; and from this it is but a short step to believe that *all* cocci are practically the same, differing only according to environment, culture media, the presence of other germs or toxins, and an infinite variety of circumstances that may affect them in ways known or unknown at the present time.

It seems folly to me to quarantine cerebrospinal meningitis and disregard pneumonia and numbers of other infectious diseases that are known to be communicable.

WHEN TO USE MEDICINES IN PNEUMONIA.*

By DUDLEY MORGAN, M.D.,

WASHINGTON, D.C.

PHYSICIAN TO GARFIELD AND GEORGETOWN HOSPITALS.

The title of this paper suggests, as the writer desires, that there are some cases of pneumonia requiring nothing but intelligent and systematic guidance and nursing, and other needing little medicine, but needing it promptly and energetically when called for.

It is a matter of surprise sometimes how well some individuals bear pneumonia. We have all had patients who have successfully weathered the storm in two or three attacks. Before beginning treatment, as well as before giving a prognosis, it is well to try and balance up the good and bad conditions which confront us. What is the condition of the heart, the kidneys, the liver? Is the patient tuberculous or does pregnancy complicate the case, etc.? It takes very little in pneumonia to cause us to be heavily handicapped. When the disease occurs in either extreme of life; the infant's life may be cut off in a convulsion, the octogenarian's may go out like a flash. A profound pneumonic toxemia will call forth all our aid to combat and woe to the patient if his life has been spent more at table d'hôte and with the wine merchant than at the frugal and simple table. There is no more unsatisfactory class of cases to attend than those who have worshiped Bacchus as one of their gods and fall a victim to pneumonia. Pneumonia is often the Good Samaritan to the inebriate and the benefactor to his friends, as it quickly and with short pain hastens him into the coma of rest and cuts short a career which could bring but sorrow and suffering to his family and friends.

Given digitalis, strychnine, and ice with the various uses, and you need little else even in your most trying cases. There is no question that many cases are lost from too much meddling in many ways. How often do we start strychnine on our first visit for no other reason than perhaps it may be needed the next day, or that we think we must give something. Quiet and rest, good ventilation, unloading of the bowels, a variety of liquid nourishing food, the ice bag to the chest in the region of the pain and congestion and one also over the precordia, if need be, is a good way to start with nearly all cases of pneumonia. 'Tis granted that there are some cases of the sthenic type, with bounding and laboring heart, high fever, pain and restlessness, and great dyspnea, in which the withdrawal of blood has been the only thing which would save life. Other most trying and often unsatisfactory cases to treat are those of pneumonia, as has been referred to, in the steady or hard drinker. Here the heart may begin to lag almost before apparent congestion and consolidation; the pulse becomes soft and compressible, the face ashy, the patient is restless, soon delirious, the temperature may not be high, but there is an impending toxemia which is and will continue to show itself in weakening and overpowering the action of the heart and the vasomotor centers. Such cases as these need digitalis and strychnine early to support the blood-vessels, bromides to quiet the restlessness, and salt solutions by hyperdermoclysis or enemata to raise the blood pressure and dilute the toxins. There is no more satisfactory way of keeping up proper elimination and sustaining blood pressure than the use of frequent saline solutions. There are many cases of pneumonia complicated with parenchymatous nephritis, which one feels quite confident were saved through this treatment.

The writer has a great repugnance to the use of opium in pneumonia, and feels that most of the cases he has lost may have been from the injudicious use of opium. There is little more needed for the cough and pain than the ice bag, but should there be, and the patient is, besides, restless, it is seldom necessary to give more than the one-twenty-fourth of a grain of morphine with fifteen grains of bromide once or twice in twenty-four hours.

In an extensive hospital ward practice many of the remedies which are suggested at the present day have been used only to be soon abandoned. There is no question that creosote may have some little palliative effect upon the cough, through the nerve filaments of the mucous membrane, that it may render the secretions more or less antiseptic and produce other slight changes, but as for any curative or abortive effect it is wasting time to consider it. To the use of nitroglycerin in certain stages of the disease, one cannot be opposed. There is a time when the right heart is laboring under the load before it in the lung, and there is an impending venous stasis, when the use of nitroglycerin or light bleeding and the giving of saline infusions have dilated the vasomotors and so relieved the heart and at the same time conserved the strength of the patient. Oxygen if needed should be used more to quiet the patient in his dyspnea and so enable him to get short naps and avoid the use of morphine. Veratrum viride has its advocates, but the good it does, if any, is not nearly so apparent in pneumonia as in typhoid or some of the fevers of the puerperium, where its beneficial use has long been established.

It is but natural, when we remember that the mortality is as great now as fifty years ago, that new methods of treatment should be proposed and heralded; the quinine-iron treatment has its backers, Page's system of fasting has had a run. The cold-tar treatment of a few years ago is hardly ever heard of; it had as its only recommendation, as Dr. Simon Baruch said, that the patient died with a fairly normal temperature. We hoped for great things from the antipneumococcic serum, but results are as yet not convincing.

It is thus that we hold to digitalis and strychnine, and are chary at adopting other drugs and their combination, believing, as Niemeyer and Jaccoud have often spoken and written, that digitalis should be used to strengthen and nourish the heart in pneumonia and reduce a rapid pulse. The words of Thomas of London in his practice in 1813 on digitalis can appropriately be repeated in our day: "Use your digitalis in pneumonia to strengthen and diminish the action of the heart."

919 McPherson Square.

*Read before the Montgomery County Medical Society of Maryland, October 16, 1906.

Results in German Tuberculosis Sanatoriums.—Remarkable success attends the treatment of tuberculosis at the sanatoriums erected in Germany in connection with the imperial workingmen's insurance, of which there are seventy-one. Nearly 88 per cent. of the patients are said to be discharged as cured or convalescent.

MEDICAL RECORD.

New York, November 17, 1906.

A FRESH VIEW OF THE CANCER PROBLEM.

AT the recent carcinoma conference held in Heidelberg, Leyden stated that the cancer investigations seemed to be on a dead center, and that some new point of view would have to be presented before progress could begin again. While this seems like rather a strong statement, it is quite true that, in spite of the claims of the sponsors of the various cancer parasites, and notwithstanding the splendid transplantation experiments that are being carried on by Gaylord, Bashford, Ehrlich, Apolant and others, the investigators seem to be but marking time; and though there is no lack of activity, there seems to be but little actual advance. For those who share this impression there will be much of interest in a communication by Bernhard Fischer of the University of Bonn, appearing in the *Münchener medizinische Wochenschrift* of October 16, 1906, which at least seems to promise a fresh point of departure for future studies. Fischer began by attempting to evoke epithelial proliferations in the skin by causing a chronic inflammatory process in the papillary layer whereby the normal relationship between connective tissue and epithelial cells should be disorganized, a factor the significance of which has been emphasized by Ribbert. Many previous experimenters have had a similar idea in view; for example, Brosch, who sought to produce the necessary irritation by applications of xylol paraffin to the contused skin, and Ribbert, who obtained papillomatous outgrowths by repeatedly scratching away the regenerating epithelium of lips of rabbits. The unsatisfactory nature of the results so far achieved in this direction led Fischer to study the effects of an irritative process in the cutis on the intact epidermis. This he set about by injecting many different organic substances into rabbits' ears; and after a large number of failures he discovered that very remarkable changes followed the injection of a saturated solution of the fat stain, scarlet-R. When such an injection is made there follow hyperemia, cellular infiltration, the formation of giant cells, and the growth of young connective tissue. At the same time the germinal layer of the epidermis is stirred to activity, mitotic figures appear, and epithelial wedges begin to penetrate into the deeper layers. The epithelial cells approach the oil droplets and then surround them, so that finally the connective tissue is permeated with colonies, wedges, and nests of epithelial cells, and presents exactly the appearance, as is evidenced by the author's numerous drawings, of an epithelioma. Fischer does not interpret these manifestations as the result of irritation in the ordinary sense of the term, but advances the theory that the scarlet-R exercises a distinct chemotactic influence on the epithelial cells. When all the oil has been taken up by the cells, the latter cease to multiply, undergo cornification, and finally cholesteotomatous masses result which break through the surface and discharge their contents. The experiment does not, therefore, result in the production of a true carcinoma, since there are lacking the properties of continued growth and destruction of tissue, but using these observations as an analogy the author offers an interesting suggestion regarding the formation of malignant tumors. Now that it has been shown that there actually exist chemical substances which possess the faculty of inducing epithelial proliferation, it is permissible to assume that there may be present in the body principles having this property. These Fischer calls "attraxins." He briefly states his theory of tumor formation, which is that cell colonies isolated from their normal surroundings in accordance with the well-known theories of Cohubeim and Ribbert are stirred into activity by the action of the attraxins. These are supposed to exist in great variety, perhaps a specific one for every variety of cell, and as the chemical qualities of the detached cell islands probably differ from those of the mother tissues, it is possible for these cells alone to be stirred into lawless proliferation.

While this is only the skeleton of Fischer's theory, it indicates the trend of his speculations. An interesting point is that Ehrlich, working along quite different lines, in the course of his transplantation experiments has come to the conclusion that, in order that the inoculation with tumor tissue to be successful, there must be present some indispensable proliferative substance, or "specific x-body," as he calls it, and it seems not impossible that the attraxine of Fischer may be identical with this supposititious agent. At any rate, Fischer has opened up a new line of cleavage, and if his own standpoint turns out to be untenable, it is more than likely that in the process of refuting or confirming his conclusions other data of importance may be brought to light.

THE RELATION OF THE STREPTOCOCCUS TO SCARLET FEVER.

IN a paper published in the *Centralblatt für Bakterilogie*, etc., Vol. XLII., No. 1, Nedrigailon critically discusses the etiological relation of the streptococcus to scarlet fever in the light of recent investigations. His article is especially interesting and timely because of the numerous reports which have lately come from all parts of the world of the successful use of the polyvalent antistreptococcus sera in cases of scarlatina. The sera of Moser, Aronson, Marmorek, and Denys have found many endorsers, and the difficult question arises whether favorable results from these sera are attributable entirely to the effect they have upon the rarely absent streptococcus complications, or whether they may be interpreted as a truly specific action upon the scarlatinal process itself.

In attempting to consider this question it will be of interest to consider briefly some of the most noteworthy investigations in this field. The pioneer worker was Croone, who, in 1885, found streptococcus in the organs of children dead of scarlatina. Similar observations were made by Fränkel and Freudenberg and, soon after, by Babes. From that time on the attention of bacteriologists was drawn to the problem, and it is quite impossible to detail the great number of facts accumulated. A few of the most convincing pieces of work, however, should be mentioned. Baginsky and Sommerfeld found streptococcus in the heart's blood of eight children who had succumbed to a fulminating type of scarlatina before any complications had developed. Class, an American physician, in over three hundred cases of scarlatina, found a diplococcus with which he was able to produce, in pigs, a disease closely simulating the human malady; there were high fever, exanthemata with desquamation, and often nephritis. These remarkable results were confirmed by Jaques, Page, and Gradwohl, and the organism in question was identified as a streptococcus. The finding of the microorganism in the throat and blood of patients during the acute stages of the disease was then reported by many workers with much unanimity and regularity. More recent investigations have attempted to establish the etiological relationship of the microorganism by means of serum reactions with scarlatinal blood. The many reports of agglutination tests have been unsatisfactory and confusing, as might have been foreseen, for our knowledge of the whole streptococcus group is, as yet, very defective, and its serum reactions are surely not group reactions, but rather more specifically limited to the individual strain or allied strains. Little advance has been made, therefore, by agglutination for either point of view.

In the face of the large number of facts, then, which seem to convict the streptococcus of being the direct causal factor of scarlet fever, it is left for us to consider the reasons for which it is, at present, absolutely unjustifiable to assume such an etiological relationship to exist. Although the streptococcus has been found with striking regularity in scarlatina, it is undeniably a common cause of complication in other diseases. It is frequently found in the throats of diphtheria patients and in the lungs of patients with pulmonary tuberculosis. Omeltschenko has found it in the blood of 82 per cent. of fatal cases of typhoid fever. De Waele and Sugg report it in the blood of many cases of smallpox and regard it, of course on insufficient evidence, as the cause of this illness.

The streptococcus isolated from scarlet fever patients has furthermore never been shown culturally or otherwise to differ from other streptococci—and in this, our present inability to distinguish definitely and exactly between the different varieties of streptococci, lies the true source of difficulty in all our dealings with this group of organisms. Finally, the complete impossibility of basing conclusions upon serum reactions obtained with the germs and scarlatinal blood definitely excludes at the present time an affirmative answer to the etiological question. Any favorable results published from the use of the antistreptococcus sera in scarlet fever must, therefore, for the present be considered as due to their effect upon the complicative organism.

Pubiotomy and the Induction of Early Labor.

Probably the value of few of the methods of modern obstetrics seems more firmly established than that of the induction of early labor in suitable cases as a conservative measure, both for mother and child. Nevertheless, a few obstetricians, notably Zweifel and Krönig, have recorded objections to the measure, principally on the ground that it is not so advantageous to the child as is usually supposed. It is alleged that the results obtained are deceptive, because, even though the children are brought into the world apparently uninjured, a very large proportion of them die before the end of the first year of life. Hunziker has utilized the statistics of von Herff's clinic at Basle by investigating the after-history of these infants, and has found that of those born at artificially premature labors, the proportion living at the end of the first year was only very slightly lower than that of those spontaneously born. Fehling (*Münchener medizinische Wochenschrift,* October 23, 1906) is a warm believer in the induction of early labor, and considers that it improves the prognosis for the life of the infant, and in this respect is superior even to cesarean section. The statistics of his clinic at Strasburg show that of the children born at twenty-seven cesarean sections only 63.6 per cent. were living at the end of the first year, whereas 82.35 per cent. of those born as the result of induced labors were living at the end of the same period. The same author also discusses the subject of pubiotomy, and states that he considers it a substitute for perforation of the living child and an alternative for cesarean section in cases of relative disproportion. He is of the opinion that pubiotomy is indicated in pelvic contractures of moderate grade, both flat and justo minor, in primiparas who are in labor when first seen. If the condition of the mother or child makes the prompt termination of the labor seem desirable, and if version and forceps are not indicated pubiotomy should be done. The same is true for multiparas who refuse cesarean section for relative disproportion, or when dystocia arises in the course of the labor through the size of the child, the presentation, etc., so that an enlargement of the pelvis is demanded for the sake of the child. From now on early labor is to be avoided as much as possible in dealing with primiparas with contracted pelves, and the province of this procedure is to be regarded the delivery of multiparas who have already gone through a still birth, difficult forceps labors, or perforation of the child. According to this author, the obstetrician should therefore not attempt to advocate either pubiotomy or the induction of labor to the exclusion of the other, but should consider both as procedures having their own special fields of usefulness.

The Cytology of Gonorrheal Pus.

The possibility of obtaining some idea of the nature of the disease process and its prognosis from the microscopical examination of the pus in cases of gonorrheal urethritis has occupied numerous observers during the last few years. The attempt has been made to determine from the preponderance of one or the other variety of cells whether the inflammatory process is still in the acute stage or has already become chronic. So far the results have hardly been susceptible of practical application,

but an interesting study made by Posner on a very large number of cases appears in the *Berliner klinische Wochenschrift* of October 22, 1906. This observer investigated smears obtained from two hundred and four cases of urethritis in males. For the most part he made use of the Jenner stain, which affords satisfactory differentiation of the leucocytes, and is very convenient in its application. He found that vacuoles could be discovered in the polynuclear and mononuclear leucocytes in all stages, and regards these as an evidence of phagocytosis, but says that they are not specific for gonococci, and do not permit diagnostic deductions. Mononuclear basophilic cells are also encountered in every stage of gonorrhea, but usually are very numerous only in the first days of the process, and in very chronic cases. Eosinophiles are invariably present, but reach their greatest numbers during the fourth and fifth week, and when very numerous they indicate that the process is gonorrheal in nature. One of the most interesting observations concerns the appearance in the secretion of a peculiar type of polynuclear leucocytes having what are termed ball-nuclei. These differ from the ordinary neutrophiles, from which they probably result through degeneration, in the peculiar spherical form of their nuclei. These stain deeply, show no nuclear structure, and have no threads of intercommunication with each other. Posner found that these cells were present in only 5.4 per cent. out of 149 smears of undoubted gonorrheal pus, and in 28 per cent. of cases in which gonococci could not be positively demonstrated, whereas out of 54 smears containing no gonococci these peculiar cells were present in 77.8 per cent. He therefore concludes that when leucocytes with these ball-nuclei are found there is reason to believe that the process has not been a true gonorrhea, or at least that the suppuration is no longer caused by gonococci alone, but is being maintained by other microorganisms or toxins.

Infant Feeding With Raw Milk.

The view that security in artificial infant feeding is to be sought in the use of a milk completely sterilized by heating has of late been criticised with more or less severity. The objectors have alleged that the heating process caused notable changes, in both the chemical and the biological properties of the milk, and that these were not negligible in their relation to the welfare of the infant. Behring went still further, and based his advocacy of raw milk on the hope of producing in the milk antibodies against certain infectious processes, particularly tuberculosis, which would be effective if the process of sterilization were omitted. The claims of numerous pediatrists who prefer unheated milk have been opposed by the views of a considerable number of observers who believe that raw milk has, at the very least, no advantages over the sterilized product. Recent experiments by Brüning (*Zeitschrift für Tiermedizin*, Vol. 10) apparently show only how complex the question is. He fed newly-born animals of the same litter partly with raw milk from a different species and partly with boiled milk. In these experiments the animals fed on the latter appeared to have the advantage, but, on the other hand, animals nourished on boiled mother's milk lagged far behind those that received it unaltered Much interest attaches to the recent efforts of Much and Romer to secure a germ-free milk without the intervention of heat. This can be effected by adding to the freshly-drawn milk a small proportion of 30 per cent. solution of peroxide of hydrogen. After having been allowed to act for a certain length of time this agent is decomposed and entirely removed by the addition of a catalyzing agent of animal origin. Tests of milk so prepared are said to show a minimal number of bacteria, while in taste and appearance the milk is entirely unaltered, and, if preserved from contamination, is said to keep for a considerable period of time. The question of whether milk so prepared actually has advantages over sterilized milk is still to be determined. Böhme (*Deutsche medizinische Wochenschrift*, October 25, 1906) made tests on a series of twelve children in Brauer's clinic in Marburg. The conclusion reached is that the milk treated in this way agrees well with children more than three months old, and that for them it is not inferior to the best boiled milk, and may even be superior. Very young, weakly infants, however, so far as it is possible to judge from the small number of cases, appear to do better on milk sterilized by heat.

Suturing Arteries.

There are three suture methods of repairing arteries which have met with more or less favor at the hands of surgeons. These are (*a*) the invagination method, (*b*) suture of the outer two coats only, and (*c*) through-and-through methods. All these, together with certain advantages, possess disadvantages, and Dr. G. M. Dorrance of Philadelphia, writing in the *Annals of Surgery* for September, describes a method of suturing arteries for which he claims many advantages and no disadvantages. Dr. Dorrance describes at some length a method of suturing a longitudinal cut, a transverse incision half way through the artery, and a complete transverse division of an artery. These descriptions are accompanied by figures illustrating the method. The method of suturing a longitudinal cut is described as follows: The clamps are applied 2.5 cm. above and below the cut. The suture is started 1.5 mm. above the cut edge; it is passed through the outer two coats and tied, and the end of the suture is grasped by a hemostat; the needle is next passed through all the coats of the artery on both sides, 1.5 mm. below the first suture and 1.5 mm. from the cut edge; the suture from now on is a continuous mattress, with the dropping back one half a suture length every third suture until the end of the incision is reached; then the needle is passed through the outer two coats, 1.5 mm. below the lower end of the cut, and a half hitch made to tie the suture. The same suture is continued as a whip stitch over the edges of the artery outside of the mattress suture until the starting point is reached, when the two ends of the suture are tied. The artery is grasped in a gauze pad, the distal clamp is removed, then the proximal clamp, and finally the artery is dropped back into place and the deep fascia is sutured around the line of approximation. We have not space to describe at length the methods of suturing the other injuries to arteries mentioned above, but these resemble in principle the method described. The advantages claimed for the method are that (1) the suture does not protrude in the lumen of the artery; (2) fibrin ferment cannot get from the ends or cut surfaces of the artery into the bloodstream; (3) the liability to secondary hemorrhage is lessened by the double line of suture. Whatever suture is used, the author insists that the principle of placing the intima to intima is absolutely essential, and the suture must be kept out of the bloodstream.

The Diagnosis of Rabies.

The rapidity with which the diagnosis of rabies can now be established in a dog, and the value of this shortened interval was well illustrated in a case reported in the daily papers a week or two ago. A mad dog bit four persons and one horse shortly before noon; by six o'clock in the afternoon the diagnosis had been established, all the persons bitten had been notified that the dog had really been mad, and one of the persons had been started on a course of Pasteur treatment. This rapid diagnosis depends on the finding, in the ganglion cells of the animal's brain, certain round or oval bodies of characteristic structure and staining properties. These bodies were first described by Negri in 1903, and have since then been studied by many other observers. The most recent and best of these studies is that of Dr. Williams of the Research laboratory, New York Department of Health. By employing squeeze smears and a special staining method devised by Van Gieson, she was able to bring out many new facts in regard to the structure of the bodies; her work makes it extremely probable that these bodies are protozoa and the cause of the disease. The great practical point in her method is the shortened time required for diagnosis, only about twenty minutes being required, instead of the 24 to 48 hours formerly necessary. The Board of Health has arranged with the Police Department to be promptly notified of every instance in which a policeman shoots a suspected mad dog. The carcass is then at once sent for and forwarded to the laboratory for diagnosis. As soon as this is established the police are informed by telephone and all persons known to have been bitten are notified by the police of the diagnosis.

The Behavior of Carbonic Acid in the Stomach.

The consumption of carbonated beverages has grown to enormous proportions, and the average individual no doubt gives little thought to their possible effect aside from their apparently refreshing character, particularly during the heated term. Americans seem especially addicted to their use, and it is safe to say that larger quantities are consumed by them than by any other nation. The carbonic acid held in suspension by the water has an undoubted sedative effect on the gastric mucosa and also a slight general diaphoretic and diuretic action. More or less uncertainty, however, has existed as to the disposition of the gas, so that considerable interest must attach to a recent communication on this subject by Loenning, published in the *Zeitschrift für klinische Medizin,* Vol. 56, 1906. He made numerous experiments in both dogs and the human subject, which show that the stomach absorbs carbonic acid gas from water in considerable quantities. This absorption occurs very rapidly, so that over one-half of the amount is taken up within five minutes and a considerable portion of the remainder within ten or fifteen minutes. The process then becomes slower, and at the end of an hour there is a small quantity of the gas left which may be absorbed very slowly or not at all. A similar condition was noted when carbonated alcoholic beverages were employed for the experiments. At the same time it was found that the stomach did not absorb any appreciable amount of the water, only two cubic centimeters being taken up in thirty minutes out of a total of four hundred which had been administered. When we consider that the body is making a constant effort to get rid of carbonic acid through the medium of the skin, the lungs, and the other excretory organs, it would appear that the intemperate drinking of carbonated beverages may not be entirely free from danger.

Tea and the Typhoid Bacillus.

An interesting observation on the effect of an infusion of tea on the growth of *Bacillus typhosus* has been recorded by an English army surgeon, Major J. G. McNaught, in the *Journal of the Royal Army Medical Corps* for October, 1906. He finds that the germ in pure culture becomes greatly diminished in numbers by an exposure of four hours to the beverage. After twenty hours it was impossible to recover it at all from cold tea. The results obtained are of interest from the author's standpoint with reference to the use of cold tea as a substitute for water in soldiers' canteens during active service. For even when water is sufficiently sterilized, it is likely to become infected after sterilization, and bottles which have once been filled with contaminated water are capable of transmitting the infection for a long time. Tea, it would seem, however, will render any chance contamination with the typhoid bacillus harmless within a few hours. A more general knowledge of this fact would soon serve to stimulate tea drinking without a doubt, as people are very apt to seize upon a measure of this kind in order to secure mental, if not material comfort. If prepared in a proper manner, tea constitutes a refreshing and not harmful beverage, for it is the tannin and other extractives which are extracted only after continued steeping that are productive of harmful consequences. If employed in the manner indicated, in localities where typhoid fever is known to be present, it may serve as one of the essential precautionary measures to guard against infection by this disease.

News of the Week.

Professor Fraenkel's Birthday. — To-day, November 17, Professor Bernhard Fraenkel of Berlin will have arrived at the age of seventy years. It was at first planned to celebrate this event by a banquet under the auspices of the Berlin Laryngological Society, of which he is the President, but as this proposal was respectfully declined by Professor Fraenkel, his assistants arranged for an exhibition illustrative of the progress of laryngology in the past fifty years, to be held in the Kaiserin Friedrich Haus in Berlin, from November 17 to 30, and this, because of its value historically, the Professor accepted. The cooperation of laryngologists throughout the civilized world was sought in the early spring of this year, and at the regular meetings of the various National Associations of American Laryngologists it was voted to participate. The matter was placed in charge of Dr. Emil Mayer of New York City, and, as a result, over 1,000 instruments, appliances, models used in teaching, etc., each bearing a distinctive tag with the word "America" stamped across the face, were sent, so that, aside from Germany, the best represented country in this exhibit will be our own. Letters and cablegrams from all over the world will be sent congratulating the Professor, who is well known as the Dean of laryngologists, for many years the head of the department of laryngology in the University of Berlin, and for nineteen

years, since its foundation, the editor of the *Archiv für Laryngologie.*

The Public Relations Committee of the Chicago Medical Society.—At a meeting of this committee, held October 23, it was decided that the more urgent public questions for the consideration of the committee are the establishment of a sanatorium for tuberculosis, the epileptic colony, and the favoring of State legislation in conformity with the federal pure food bill, including the labeling of preparations containing habit-forming drugs. It seemed proper to leave the question of the State tuberculous sanatorium and the epileptic colony in the hands of the State Board of Charities for the present. The committee has decided to obtain the views of the candidates for the State legislature as to whether they would favor a State law conforming with the federal pure food law, passed at the last session of Congress, requiring the labeling of preparations containing habit-forming drugs. At the meeting of the Illinois State Medical Society, held May 16, at Springfield, a resolution was passed instructing the Committee on Medical Legislation to work for the passage of a bill by the next General Assembly of Illinois, which shall provide that all bottles or packages containing drugs shall bear a statement on the label of the quantity or proportions of alcohol, narcotics, or other poisons which may be contained therein.

McCormick Memorial Institute.—After several years' effort, the McCormick Memorial Hospital for Children suffering with infectious diseases, has secured a site at the northwest corner of Fifty-fourth street and South Park avenue, Chicago. Prejudice on the part of property owners has thus far prevented the consummation of the project, in spite of the fact that the Chicago Medical Society and individual physicians all over the city went on record as vouching for the safety of a neighborhood in which such an institution would be located. Mr. McCormick's plans provide for a modern hospital, located on spacious grounds, equipped according to the best scientific knowledge of Europe and this country. Provision for charitable work on a large scale has been included in the plans.

Chicago Board of Health Laboratory.—The latest bulletin of the Chicago Board of Health shows that the local physicians are increasingly availing themselves of the facilities afforded for the bacteriological diagnosis of disease. The number of throat cultures received in the laboratory during October, 1906, shows an increase of 138 per cent. over the number received in the corresponding month of last year, and the number of specimens of blood to be tested for typhoid fever shows an increase of 69 per cent. There is no such increase in the mortality from these two diseases. On the contrary, there were only seven more deaths from diphtheria, while there were six fewer from typhoid fever in October this year than in the corresponding month of 1905. The Health Department officials believe that the practically stationary diphtheria mortality and the reduced typhoid mortality are related to the increasing use of the laboratory.

Mosquitos on Staten Island.—Dr. A. H. Doty, Health Officer of the Port of New York, announces that the *Culex solicitans* or striped-legged mosquito has been practically exterminated in Staten Island. This is the result of the expenditure of $17,000 in draining several of the marshes on the island. Some other members of the family still remain to be dealt with, however, but it is hoped that when the New Jersey swamps opposite Staten Island have also been drained mosquitos will be rare in Richmond.

Hospital Bequest.—By the will of the late Margaret Agnes Weiher, wife of Dr. Charles L. Weiher of this city, and daughter of the late John and Mary Sheehan, $1,000 was bequeathed to the St. Joseph's Hospital for Consumptives.

Washington Heights Hospital.—According to the first annual report of the Washington Heights Hospital 2,000 patients have been treated in the dispensary, and about 1,000 in the hospital in the twelve months, but the gifts received from the patrons have not been adequate for the maintenance of the institution.

Dr. George F. Shiels of this city has been awarded a Congressional medal of honor for distinguished gallantry in action at Tuliahan River, Luzon, P. I., March 25, 1899, when he was serving as Brigade Surgeon with rank of Major under Gen. Wheaton.

Internes Resign.—The six internes comprising the house staff of the German Hospital in Williamsburg resigned in a body last week. The cause of this action was alleged to be the interference with the work of the doctors by the head nurse of the institution. The climax came, it was stated, when this nurse countermanded a prescription ordered for a patient by one of the staff, and, as a result, the resignations of the directors were handed in and accepted.

A New Public Bath.—Plans for a new three-story public bath and gymnasium to be built at 342 to 348 East Fifty-fourth street, have been filed with the Building Department. It is to have a frontage of 75 feet and a depth of 100 feet, with a classic façade of brick trimmed with granite and limestone, ornamented with large columns supporting a cornice and balustrade. Separate baths for men and women will occupy the first two stories, and the top floor will contain the gymnasium, and a mezzanine story will be used for a running track. The building is to cost $200,000.

Suit by a Physician.—A Philadelphia physician has brought suit against the estate of a deceased wealthy patient for the sum of $33,000 for professional services. He was engaged by the patient to travel with him, and was to receive $300 a day for his exclusive services. During 1903 and 1904 the indebtedness accumulated to the amount mentioned.

Experimental Surgery.—A department of experimental surgery has been established in the medical school of the University of Pennsylvania, and Dr. J. E. Sweet, formerly connected with the laboratory of hygiene, and more recently with the Rockefeller Institute, has been placed in charge.

Kissing Games Barred.—The health authorities of Malden, Mass., have set themselves in opposition to the forces of nature by announcing that no more kissing games are to be allowed in the city. This is because of several recent deaths from diphtheria among school children who have taken part in such amusements.

Sanitation in Havana.—In consequence of the deplorable conditions which have been found to exist in the National Insane Asylum at Havana, Gov. Magoon has decided to expend the sum of $29,000 for immediate repairs. A total sum of $160,000 has been appropriated to be used for this

purpose. The authorities are also insisting on compliance with sanitary regulations by the proprietors of cafés and restaurants, most of which are extremely deficient in their toilet accommodations.

The Birth Rate in France.—That the preference of French married couples for small families has not been modified is shown by the publication of the vital statistics for 1904. The births in France for the year numbered 807,292, showing a decrease of 10,937 from the total of 1904. The reason for this decrease is not to be found in a reduction of the number of marriages, in which the statistics show a slight increase over 1904, but it apparently arises from the aversion of the French people to large numbers of children. The National Association, which is studying this matter, has reached the conclusion that it is necessary to inculcate the idea that any couple that raises more than three children merits and is entitled to public gratitude and protection.

Lombroso a Spiritualist?—The newspapers report that much interest has been aroused by an article by the celebrated alienist, Prof. Lombroso, in the current number of *La Tetura,* dealing with the phenomena of spiritualism. The interpretation of the article appears to be that it is a frank recantation of Lombroso's antispiritualistic theories, which, so far as can be judged, seems to have been brought about by ordinary enough samples of so-called spiritualism.

Death of the Smallest Man.—The death of what is said to have been the smallest man in the world occurred last week at Wilkesbarre, Pa. The name of this personage was Reese Wiggles. He was born in Wales fifty-three years ago, and is said to have been but thirty-seven inches tall, or four inches less than Gen. Tom Thumb.

Tuberculosis Among Mill Workers.—Very encouraging results are reported by some of the mill owners of Rhode Island, who are endeavoring to combat tuberculosis among their employees. These firms have engaged physicians, who supervise the workers and give instruction in hygiene. The mill hands are cooperating with much interest, and it is expected that within a short time an effective organization will be at work throughout the entire State.

Dr. Grenfell Honored.—Dr. Wilfrid T. Grenfell, the medical missionary who founded and conducts the Labrador Deep Sea Mission, was among the recipients of the King's birthday honors, being created a Companion of the Order of St. Michael and St. George.

The Bradshaw Lecture before the Royal College of Surgeons of England will be delivered by Mr. Edmund Owen, December 12, the subject being "Cancer; Its Treatment by Modern Methods."

Medical Association of the Southwest.—At the meeting of this society, held at Oklahoma City October 31, Hot Springs was selected as the place for the next meeting. The following officers were elected: *President,* Dr. C. M. Rosser, Dallas, Tex.; *Vice-Presidents,* Dr. R. P. Runwan, Little Rock, Ark.; Dr. W. F. Sawhill, Concordia, Kan.; Dr. John Punton, Kansas City, Mo.; Dr. E. O. Barkef, Guthrie, Okla.; *Secretary and Treasurer,* Dr. F. H. Clark, El Reno, Okla.

Brooke County (W. Va.) Medical Society.—A medical society for Brooke County, W. Va., was organized at a meeting of physicians recently held for that purpose at Wellsburg. Dr. C. A. Wingerter of Wheeling, ex-councilor of the State society, was present as organizer. The officers chosen are as follows: *President,* Dr. J. B. Walkinshaw, of Wellsburg; *Vice-President,* Dr. B. S. Hardin; *Secretary,* Dr. C. R. Weirick; *Treasurer,* Dr. J. P. Johnson; *Board of Censors,* Drs. Gist Palmer, J. L. Pyle, and W. T. Booher.

American Therapeutic Society.—The next meeting of this organization will be held in Washington, D. C., March 4, 6, and 7, 1907. The officers of the society are as follows: *President,* Dr. Robert Reyburn of Washington, D. C.; *Vice-Presidents,* Drs. Joseph E. Janvrin of New York, Frederic H. Gerrish of Portland, Me., and Howard Van Rensselaer of Albany, N. Y.; *Secretary,* Dr. Noble P. Barnes of Washington, D. C.; *Treasurer,* Dr. John S. McLain of Washington, D. C.

In Memory of Schaudinn.—The German Dermatological Society has decided to subscribe 5,000 marks to the Fritz Schaudinn memorial fund and to issue the first volume of its transactions as a memorial to the deceased investigator.

Obituary Notes.—Dr. Charles Vose Bemis of Medford, Mass., died on November 6 at the age of ninety years. Dr. Bemis was one of the oldest graduates of Harvard College, receiving his literary degree in 1835, and his medical degree four years later. He began to practise in Medford shortly after his graduation, and had lived there ever since. He was for some years trustee of the Massachusetts General Hospital.

Dr. David Henry Hazen of Washington, D. C., died on November 6 at the age of sixty years. He was born in Upper Mount Bethel, Pa., and went to Washington in 1870 to study medicine. He was a member of the District of Columbia Board of Education from 1890 to 1900.

Dr. William J. Brunner of this city died suddenly of heart disease on November 9. He was born in Germany, but came to this city while still a youth, and was graduated from the New York University Medical School in 1879. Since his graduation he had practised in this city.

Dr. Samuel H. Gordon of Newark, N. J., died suddenly of heart disease on November 10. Dr. Gordon was thirty-five years old, and had received his medical degree from the Medico-Chirurgical College of Philadelphia.

Dr. J. C. Schrader of Iowa City, Ia., died on October 30 at the age of seventy-six years. He obtained his medical education at the College of Physicians and Surgeons, Keokuk, and at the Long Island College Hospital, receiving his medical degree in 1870. He was for many years professor of obstetrics and gynecology in the College of Medicine in the Iowa State University, and was long the Dean of the faculty. In 1898 he resigned and was made emeritus professor. Dr. Schrader was State Senator for two terms, and held many medical and official positions, including the presidency of the State Board of Health, of the State Board of Medical Examiners, and of the State Medical Society. He had also been vice-president of the American Public Health Association and of the Western Association of Obstetricians and Gynecologists.

Dr. Walter Langdon Hall of Medford, Mass., died on November 1 after an operation for appendicitis. Dr. Hall was born in Augusta, Me., in 1846, and was graduated from the Bellevue Hospital Medical College in 1867. After serving several years in various New York institutions, he began practise in Gardner, Me. He removed to Newcastle, Me., where he practised seven years, and then settled in

Medford. In 1886 he was made professor of medicine at the Boston College of Physicians and Surgeons, and in 1893 was given the same chair in the newly founded Tufts College Medical School. He gave up practise in 1898, and since then spent much of his time in Mexico.

Dr. Julian Abbitt of Appomattox, Va., died on November 1 at the age of thirty-eight years. He was a graduate of Richmond Medical College.

Dr. M. A. Brown of Marshall, Mo., died on October 30. Dr. Brown was born in Albemarle County, Va., in 1833, and in 1861 was graduated from Jefferson Medical College, Philadelphia. He served through the Civil War as a surgeon in the Confederate Army, and had practised in Marshall for many years.

Dr. Silvester L. Nidlet of St. Louis died on October 30 at the age of seventy-seven years. He was born in Philadelphia, but removed to St. Louis in 1844, and was graduated from the St. Louis Medical School eight years later. He served through the Civil War as surgeon, and later was appointed chief surgeon of the Whetstone Indian reservation.

Dr. Clarence W. Spring of Fitchburg, Mass., died on November 2 after an illness of several months. Dr. Spring was born in Salmon Falls, N. H., in 1859, and was graduated from Dartmouth College in 1880. Four years later he received his medical degree from Harvard Medical School. He had practised in Fitchburg since 1885. He was City Physician for two years, and served many terms as secretary of the Worcester North Medical Society.

Dr. David B. Birney died at Philadelphia on November 2 as the result of an accident. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1885.

Dr. T. Stanton Crowly died at Philadelphia on November 7 at the age of eighty-three years. He was graduated from Jefferson Medical College in the class of 1849.

Dr. Wm. Shafer died at Camden, N. J., on November 8 at the age of fifty-three years. He was graduated from Jefferson Medical College in the class of 1884.

THE SECOND HARVEY SOCIETY LECTURE.

The second lecture in the present series given by the Harvey Society was delivered in the New York Academy of Medicine on Saturday, November 3, by Prof. C. A. Herter, the subject being "The Common Bacterial Infections of the Digestive Tract, and the Intoxications Arising Therefrom."

The speaker began by a discussion of the intestinal bacterial flora, and stated that the alimentary tract of the higher animals contained from 200 to 300 billion bacteria, of which about nine-tenths are dead. Many observers had claimed that the presence of bacteria in the intestinal tract was necessary for the normal life of animals, but the experiments of Nuttall and Thierfelder indicated that this was not so. While, of course, it was impossible to exclude bacteria from the alimentary tract under ordinary conditions, the speaker believed that this presence was not essential for the life of the host. The bacterial distribution in the tract bore a definite relation to the environmental conditions. He had found *B. lactis aërogenes* to predominate in the upper part and *B. coli* in the lower. Regarding the latter the speaker believed that by utilizing undigested food residues available for other organisms, and by inhibiting the growth of these competitors through acid formation, *B. coli* might play a serviceable rôle.

The studies of Dr. Wakeman had shown that conditions in the colon were very largely anaërobic, while the small intestine was aërobic to within a foot of the ileocolic junction. In disease anaërobic organisms invaded and thrived in the small intestine. Curiously enough, the passing of oxygen through the tract seemed to have no effect in changing the results of certain experiments bearing directly on this point, nor did the administration of peroxide of hydrogen, together with catalytic ferrous sulphate produce any change. It was found that conditions favoring anaërobic growth were associated with the rapidity of digestion and resorption. The increased anaërobic condition of the alimentary tract was found to have an important bearing on the number and variety of the bacterial contents. Clinically, the insufficiency of oxygen in the blood of anemic individuals caused the intestinal tract to become abnormally anaërobic.

Prof. Herter then spoke of the microscopical examination of the stools, and said that the gram stain afforded considerable information. He had found, for instance, that diet had a pronounced effect on the number of gram positive organisms present. With animals partaking largely of proteid food the feces showed numerous organisms staining gram positive. On a carbohydrate diet there was a predominance of gram negative organisms. Dr. Herter had examined the feces of the lion, tiger, wolf, and cat; all of these showed a large proportion of gram positive bacilli, and free spores. Similar examinations in the case of the buffalo, goat, camel, and elephant differentiated an herbivorous type of bacterial flora having practically no gram positive bacilli and few spores. He had inoculated the feces into broth, and had found a production of mercaptan only in the flasks inoculated with carnivora feces. When emulsions of feces were inoculated into guinea pigs there was also a marked difference between the carnivora feces and those from the herbivora. With the former there resulted hemorrhagic edemas and digestion of tissue extending into the connective tissue. On autopsy gas and butyric acid formation could be demonstrated. The effects were similar to those produced by *B. aërogenes capsulatus*. With herbivora feces there was an entire absence of these pathological effects, or they were but slightly manifested. A clinical fact which fitted here was that carnivora frequently suffer from anemic troubles, while pernicious anemia rarely occurs in herbivora unless associated with gross parasites.

Taking up the bacteria in the human alimentary tract, Prof. Herter said that especially in the young the number of spores and spore-forming bacteria was relatively few. With advancing age and tissue impairment there was a roughly corresponding increase both in putrefactive bacteria and in their products excreted. The distribution of these putrefactive bacteria varied, he said, with the local degree of anaërobic condition; they were most numerous in the lower small and in the large intestine. An exception to the factor of age was found in the occurrence of types of these organisms, especially *B. bifidus*, in the tracts of nursing children. In those conditions of the young characterized by marasmic growth, distended abdomen, and pasty movements, *B. bifidus* is the predominating organism. Herter examined the feces in a case of appendicitis and found the gram positive bacilli, diplococci, and sporebearers to be the predominating types. He

thought that these, perhaps, were an important factor in the disease. In some instances, *B. coli* might be replaced, temporarily at least, by organisms of aberrant type. This substitution, he believed, was an extremely common phenomenon.

Considering next the bacteria causing infections in man and higher animals, the speaker divided these into three classes. First, the *B. coli* type, endotoxic in character, the extreme variation from which was the typhoid organism. Second, the dysentery group of bacilli, elaborating to some extent soluble toxins which caused similar lesions to those of the actual infection, and produced, at times, neuritic types of disease. Lastly, there were the putrefactive organisms which were spore formers, strict anaërobes, and pathogenic. These liberated hydrogen and formed butyric acid. They also initiated proteid decomposition, though the indol, etc., were then directly formed by other organisms, such as *B. coli.* Under this class of putrefactive organisms were included *B. putrificus, B. botulinus, B. aërogenes capsulatus,* and *B. enterogenes sporogenes.*

According to Herter, the chronic excessive intestinal putrefactions were of three types: (1) the indolic type, where infection is by anaërobic forms associated with *B. coli;* (2) the saccharo-butyric type, especially *B. aërogenes* and *B. putrificus.* This type was characterized by flatulence, gradually developed (at times acute) anemias, and the production of hemolytic substances. There was also a diminution of *B. coli* in the tract and marked increase in the anaërobic production of mercaptan; (3) the third type was really a combination of types 1 and 2, in which nervous symptoms were early prominent, and which later showed both nerve and hemic disturbance.

The lecturer called attention to the difference in the effects of putrefactive products on normal and on weakened individuals. Indol, for example, was borne in considerable quantities by healthy persons without deleterious effects; it was easily oxidized and conjugated to indican. The experiments of Richards were mentioned; these showed that dogs whose oxidative powers reduced by poisoning with hydrocyamic acid were very readily poisoned with indol while normal, untreated dogs bore much larger doses without ill effects. In the hydrocyanic acid dog the power of oxidizing and conjugating these putrefactive substances was much diminished. An indicanuria in sound individuals, then, might merely indicate that large quantities of putrefactive products were well handled and promptly disposed of. According to Lee, indol diminished the irritability of frog muscle and mammalian muscle perfused with indol solution, 1-25,000, did only 37 per cent. of the work of the normal control. For the physician, it was important to remember that in persons whose oxidation capacity is reduced, or who are subject to prolonged and excessive intestinal putrefaction, free indol in the circulation may do considerable harm.

Among the criteria which the speaker gave as an index of the intensity of the infections were the elimination of the products of putrefaction, the character of fecal gram fields, and the clinical symptoms. The prognosis was unfavorable when there was progressive loss of strength and weight, marked anemia, Ehrlich aldehyde reaction, and disappearance of *B. coli.*

The treatment recommended by the speaker was along the following lines: (1) The avoidance of putrefactive organisms (ordinarily introduced with the food) through oral and gastric cleanliness, and the employment of lavage in retention; (2) the promotion of prompt digestion and absorption from the small intestine by improving the secretions through absolute rest, by hydrochloric acid and enzyme administration, thorough mastication, and the avoidance of irritants and excessive food; (3) the treatment aimed to combat the putrefactive organisms with gastroenteric antiseptics, laxatives, lactic acid bacteria, irrigation of the colon, etc.

Correspondence.

FEDERAL INSPECTION OF MILK.

To the Editor of the Medical Record:

Sir:—The man who first attempted to reform the farmer in the ways and means of milk production was the manufacturer of condensed milk. He knew only too well the filthy condition under which milk was made, but accepted them as a necessity, and his promptings on the score of neatness, cleanliness, and sanitary surroundings were not matters of inward consciousness. When the cans of milk were spread about in the avenues of commerce, letters of complaint came in. The milk was spoiled, in spite of the sugar added to preserve it, or, when opening the can, the odor of manure greeted one's nostrils. The making of condensed milk promised untold fortunes for those engaged in it, and something must be done to remedy the evils existing, which produced dirty milk that was likely to make the condensing business a failure.

So, realizing that it costs money to be clean, the condenser put a premium on cleanliness, care, and intelligence in the production of milk by paying the farmers so much more a quart—and then, to insure against the economic tendencies of the farmer prompting him to put the premium in his pocket and forget all about the cleanliness, they insisted on the farmer signing a contract to make clean, wholesome milk.

The milk the farmer put on board the train, to be sold in the city at so much a quart, the condenser cared not how it was made; he was not interested. If the cows drank from slimy, green, mosquito-breeding horse-ponds; if they were fed on acid, vinegary, refuse brewers' grains, distillery swill; if fed upon fermenting ensilage; if the stables were never whitewashed from one end of the year to the other, and poorly ventilated; if the cows were allowed to wallow in their filth, encrusting deeply the bag and teats; if milk was taken from cows immediately after calving; if the milk from the suppurating and bloody udder "went in with the rest;" if the milk went into the can, and with little or no cooling or aerating, further than the ice packed on top of it in the car, and the shaking up it got; if the utensils were slimy and cheesy with the residue of former milkings; and if the men who milked the cows found it simpler and easier at 2 A.M. to not only wash their own hands in the milk, nice and warm from the cow, but to use it in cleansing the manure-coated udder and teats, the condenser cared nothing for this, and it was none of his business if practised by the farmer who sent his milk to town. But for condensing purposes clean milk must be used, and that only. So, when a farmer came to him, complaining of the tyranny of the milk-exchange and of the irresponsible milkman who refused to pay at the end of the month, and wanted to deal with the condensery near at home, where his pay was certain and there was a premium of half a cent a quart, the condenser then and there agreed to take his milk, *provided* he signed and lived up to the contract, submitted to inspection, and became subject to a fine of no inconsiderable amount for infractions of any kind.

And so the farmer fenced in, and away from the cattle, the frog-ponds; cut out the swill feed and ensilage; cleaned, and kept clean, his now whitewashed stables; saw that the stalls were cleaned and the cattle properly bedded; saw to the washing of udders and teats before milking; took milk to the condensery only from healthy cows; put his cans into the spring house, stirring them when cooling; scoured and sun-bleached his strainers and milk cans and pails for hours daily in the air and sun, and insisted upon the cleanliness of the help who did the milking. And this is how the milk used for condensing became sweeter and cleanlier than that made for daily consumption in the cities.

Milk is the most changeable and easily affected food that comes upon our table. When put into the refrigerator care is taken to seal up tight the bottle that holds it, lest it absorb the odors of other foodstuffs in the next compartment. Yet that milk, when taken from the cow, stood open in cans exposed for an hour or more to the odors of a reeking stable, in which thirty or forty cows were confined over night. Delightful to contemplate!

We have heard so much about the packers and their infamies that with some, and perhaps many, people to-day the sight of meat proves nauseating. The presence of canned meat in the family larder, horrors! But the uncleanliness of the stable-made milk, the mainstay of the helpless little one, is many hundred times worse than the ante-jungle condition of the packers. If the millions of milk-fed infants could, out of their helplessness, intelligently express themselves, they would in one voice cry out to the national government for the same consideration shown their parents, and ask for *Federal Milk Inspection.* Those who are inclined to smile at such food-scare articles as these should visit a creamery, where machine-made cream is produced. This is done by revolving hollow, pumpkin-shaped steel bowls 8,000 to 9,000 times per minute and passing the milk through them, a separate stream each of cream and skimmed milk leaving the separator. This mechanical skimming is done by centrifugal force, the heavier bodies—water, casein, milk-salts, manure, blood, pus, seeds, dust, and foreign matter—being thrown to the outside of the inside circumference of the bowl, and the lighter body—the cream—being held at the center.

Now, remembering that before separation such milk was passed through seven or eight strainings, stand by one of those separators when the run is over and see the bowl cleaned out. The milk-filth packs in a long, thick layer around the inside of the bowl. See one of those strips of filth stripped from the separator, and then examine it. No magnifying glass is necessary. There's the manure, plain as day, increasing or lessening, according as to whether it is winter barn-made milk or summer out-door milk. Blood and pus, not always, though frequently present; hairs, seeds, and dirt galore. It's there. You can see it without the aid of a microscope, nor do you want an analytical chemist to tell you by means of furnace, acids, test-tubes, etc., what they are. If you wish you may go and visit the stables and see the cause for all this; but, as to results, here they are in unmistakable signs in front of you.

Now, sterilization and pasteurization are, in their way, grand, and of the utmost usefulness. Strauss has proven this in a practical way. But is it not proper that the spring with the dead hog in it should be purified and cleansed rather than that the water coming from it should be boiled and filtered?

Federal Inspection of Milk! Phew! What a problem! Of course. But if a butcher, through a system of inspection and licensing, can be prevented from sending forth as food for human consumption trichina-infected hogs and tuberculosis-infected cattle, why cannot a plan be evolved to license the farmer along the lines of cleanliness and the making of sanitary milk in all that the word implies?

Someone—not a railroad director—has said that a human life is beyond all monetary computation; when taken, or lost, it can never be replaced. Now, if it is the saving of a single infant from an untimely end by Federal milk inspection, then alone would or should that compensate for all the trouble and expense that the government might assume.

But the fact stands that, with a few exceptions (so rare that, when we are aware of them, we exclaim in wonder at the cleanliness of the stables), the milk sold and consumed daily is by far the most filthily produced and the most unsanitary food that goes upon the family table to be fed to the infant, whose powers of digestion and assimilation are immature, to say the least.

But facts are facts, meet them as we may.

CHARLES CRISTADORO.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HARVEIAN ORATION—CALCIFIED FIBROIDS—MEDICAL SUPERVISION OF SCHOOL CHILDREN—VACCINE—TEMPERANCE HOSPITAL—OBITUARY.

LONDON, October 26, 1906.

PROFESSOR OSLER delivered the Harveian Oration at the Royal College of Physicians, the president, Sir D. Powel, occupying the chair. The subject which Dr. Osler proposed to illustrate by Harvey and his discovery was the gradual growth of scientific truth through the stages of acquisition, latent and conscious. Harvey's student days at Caius College, Cambridge, and the influence of the writings of John Caius were considered, also his work at Padua under Fabricius, whose teaching moulded Harvey's subsequent career to such an extent that it appeared almost incomprehensible that he should have missed the inspiration which grew into the great truth of 1616 on that memorable April day, when, in the Parlor Lecture, as it was called, in the Anatomical Theater, Harvey set forth his anti-Galenical doctrine as to the circulation, justifying the proverb that "they alone discover what they prove." While men of authority admitted the lesser circulation, there is no evidence that the lecture, which was delivered in Latin, had any immediate influence on the profession of the time. Such a heresy, indeed, as the general circulation could hardly have been appreciated. We cannot even say whether it actually modified Harvey's own practice in any way. It is a remarkable fact that he delayed for twelve years the publication of his views. But similar reticence has been a marked mental feature of some of the greatest discoverers, notably of Newton, who brooded for twenty years over the principle of cosmic circulation which he had grasped, and again of Darwin, who delayed for a similar period the publication of his theory. The present generation has succeeded in making knowledge effective by the fruitful application of truth to human purposes.

After the oration the Moxon medal was presented by the president to Mr. Jonathan Hutchinson.

At the last meeting of the Gynecological Society, Mr. Bowreman Jessett, president, showed a specimen from a case of pedunculated multiple fibroids undergoing calcareous degeneration removed by celiotomy and enucleation of the tumors. He related the case and commented upon some of the most salient points. The history was rather unusual; ten years ago he had removed the left breast for scirrhus; recurrence in axilla three years later; removed; another three years elapsed and then another operation had to be done in the same axilla, since when no recurrence for these four years. The patient sought advice this autumn for pain in the left side of her back and down the leg, which prevented her from walking. Her doctor found something in the pouch of Douglas and sent her again to the president, who operated on September 18. Five nodular pedunculated tumors were removed, and the patient made an uninterrupted convalescence. Mr. Jessett said his case showed the importance of pains extending from the leg as a symptom which may be due to pressure on the sacral and lumbar plexus. If a growth is present it can be removed. Another interesting point is that the tumors were completely calcified. In elderly women all fibromyomata are apt to become so in either form—peripheral or interstitial. In the former a thin, rough, chalky deposit is found on the surface; in the latter there is infiltration through the thickness of the tumor, either in patches or generally diffused. Such calcified tumors were described by Hippocrates. Mr. Jessett has now under his care a similar case, from which he removed a scirrhus breast several years ago, but he finds fibroids following scirrhus have been so rare in his practise that, contrary to the views of some, he thinks the sequence of no importance.

In discussing this case most speakers seemed interested in the fact that the patient had survived so long after malignant disease and then developed these fibroids, but one or two agreed that there was no relation between the two diseases, particularly as uterine cancer is often found together with fibroids.

Dr. H. Smith thought the two diseases quite independent and that the fibroids were developing before the cancer; in fact, that they, when small, set up irritation in the breast, which degenerated into scirrhus. The fibroids might have remained small and grown again later.

Dr. Howell Evans said a fibroid might be dormant for years and then suddenly burst out, and a crop of tumors appear. Patients of twenty-one to thirty were seen complaining of symptoms impossible to impute to fibroids, and five, ten, or more years later might appear with a crop of fibroids like a potato tuber. It was remarkable that in the president's case a condition of malignancy existed for years, and afterwards calcification—a natural protective condition—was found in a benign tumor. Could it be that a tendency to fibroids and calcification might be so great as to give rise to that rare occurrence, expulsion by nature of a malignant tumor? Dr. Dauber did not find calcified uterine tumors uncommon. The condition was only due to long duration.

Mr. C. Ryall said in such cases as the president's enucleation was certainly correct treatment. Such fibroids had passed the growing stage and were degenerating, when there were one or two hard fibroids tending to calcification; especially in young women, enucleation was also advisable. It was not justifiable to remove the uterus for one or two such in young women, but in multiple cases it might be right to do hysterectomy.

Dr. Swanton said patients with calcified fibroids had symptoms of pressure of uremia and little else. The mortality from operations for fibroids seemed to be high from Piquand's statistics, viz., 12 per cent., as against 3 to 5 per cent. of fibroids generally. He also asked about the condition of the ovaries.

The president, in reply, said he had removed the ovaries in several cases as a last resort in cancer of the breast, but

he had never seen any improvement follow. He had no doubt that the fibroids had been of long duration, and it was only when calcification developed, and pressure on nerves set up radiating pain down the leg, that it compelled attention. He could not say whether there had been any calcification in the mammary cancer. He agreed generally that enucleation was bad practice, because so often there were more interstitial fibroids that could be detected. When subperitoneal calcified tumors were found at the age of this patient (fifty-one) there was not likely to be further trouble, so he enucleated all. They came out easily and he had no trouble with hemorrhage. In some deeply-seated interstitial cases it was difficult to arrest the bleeding. The ovaries were small, but quite healthy and not removed. He thought if this patient's fibroids had not calcified she would have had no pain whatever. He had not had sufficient cases to enable him to form an opinion on the mortality after operation.

The Medical Supervision of School Children was the subject of a discussion which was, for the most part, rather an advocacy, at the Parkes Museum this week. Mr. Macnamara, M.P., presided, and said directly the doctor went into a slum school exposure would be made, which would fill the public with shame. It had been partially done, but the London system was roundabout, and was mostly concerned to compel parents to cleanse their children's heads. Liverpool was far ahead. There, in 23 out of 152 schools, nurses regularly attended to those children who had been picked out by the teachers—about 10 per cent. in the poorer schools. Professor Kenwood said to preach the value of medical inspection to that audience would be preaching to the converted. The best education needed the best physical condition. The teachers knew that, and knew medical inspection was needed, and the central authority was to blame for subordinating hygiene to mere instruction. Inspection was specially of value as to sight and hearing, the two faculties through which instruction was received. Mrs. Dr. Scharlieb and Dr. Hyslop also spoke in the same sense.

Dr. Alan Green has contributed to the report of the medical officer of the local government board his further observations on his chloroform process for eliminating extraneous organisms from calf vaccine lymph. He finds that it is best to defer the addition of glycerine until the chloroform has completed its action. The combined influence of chloroform and glycerine in water appears to be prejudicial to the vaccine. Dr. Green was not able to completely eliminate spores from pulp to which a spore-bearing organism had been added, by employing chloroform after the plan of fractional sterilization. But the numbers of spores have been greatly reduced by this process. Germination of spores took place after the application of the chloroform, and some during its continuance, so that the propagation of organisms was carried on, although in greatly diminished numbers.

The foundation stone of the new buildings of the Temperance Hospital was laid yesterday by Lady Strong and Sir T. V. Strong presided over an influential meeting in support of the institution—the president, the Lord Chief Justice, being detained by his judicial work. The reconstruction was undertaken at the suggestion of King Edward's Hospital Fund. The first part will cost £11,000, of which above £3,000 was promised before the proceedings began, and £1,063 was laid on the foundation stone at the meeting.

William Sedgwick, M.R.C.S. (1845) died on the 20th inst., aged 85. When dresser to Liston, he was present at the first operation performed in London under anesthetics. After taking several voyages to India and China, mostly in charge of troop ships, he settled and practised in London. He devoted great attention to the study of heredity, and this work was acknowledged by Darwin as most useful. He also contributed several papers to societies and journals on cholera, the latest of which was probably his address as president of the Harveian Society, 1889, which he devoted to "Cholera and Chemistry." For some years he has been retired.

Dr. E. Drummond died on the 20th inst. He was well known as the English physician in Rome. He translated the volume of memoirs on malaria for the new Sydenham Society and contributed to journals and societies on the condition of the Roman Campagna and on local fevers and various climatological questions. He graduated M.D. Edin. 1864. He returned to England several years ago, and devoted much attention to bacteriology.

Lieut. Col. A. W. Bate, M.D., died on the 22d, aged 64. He entered the army medical service in 1865 and retired in 1885. In that year he had served in the Soudan campaign, and was awarded the medal and the Khedive's star.

Lieut. Col. C. S. Wills, C.B., A.M.S., died on the 12th inst., aged 73. He joined the army medical department in 1857 and retired in 1899. Since then he devoted his energies to philanthropic and religious work, chiefly in Lancashire.

Dr. Joseph May, J.P., died on the 8th inst., at the advanced age of 90, at Rathfriland, County Down, where he had practised all his life and was greatly esteemed and beloved.

A premature death seems that of Dr. Tom Walker of Manchester, who has died at 37 after a remarkably strenuous career. He began as a pupil teacher in a Board school, won a scholarship to a training college, and qualified as a schoolmaster; worked at teaching for six years; took the B.Sc. Lond. Then, having reached his 28th year, he turned to medicine, entered Owen's College, won a scholarship, took his double qualification (1901), the M.B. 1903, and B.S. 1905. He was for a time a demonstrator at Owen's College, and filled the various house appointments at the Royal Infirmary. He hoped to become medical officer of an educational authority, for which his qualifications seem to show he was most suitable, and those who knew him assert that his personal fitness was just as exceptional.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CHOLERA — REMOVING LEPERS — TRIAL OF CHOLERA SERUM—NEW CIVIL HOSPITAL TO BE BUILT—RETURN OF DR. STITT OF THE NAVY.

MANILA, Sept. 30, 1906.

THERE has been a great improvement in the cholera situation in Manila, and the Island of Luzon generally. Only a few scattered cases per day are being reported, but the disease in the Province of Iloilo, of which mention was made in the previous letter, has been slowly spreading, and there have been a total of 574 cases and 463 deaths since the outbreak in the early part of September. Cultures taken from some of the cases at autopsy were forwarded to Manila for examination, and the Bureau of Science reported that the cholera spirillum of Koch was positively present, thus absolutely confirming the presence of the disease in that province. The disease had been diagnosed as cholera nostras, and, notwithstanding the fact that the death rate in some of the towns had increased eight or ten per day over the normal rate, yet it was only after the positive confirmation of the Bureau of Science, and after the activity of the Insular health officials was seen, that the local authorities were awakened to the reality of the danger which threatened them.

There could be no stronger argument in favor of the need of more and better facilities in the education of the native physicians in the provinces, and for the elimination of the *mediquillo* and *practicante*. If the nature of the disease had been recognized in the beginning, and proper measures taken, it would probably have been an easy matter to stamp out the infection, and hundreds of lives and thousands of dollars in money would no doubt have been saved.

The campaign against cholera which was inaugurated in the Province of Tayabas was brought to a successful conclusion during the latter part of September. This is another example of what may be accomplished when modern methods are intelligently applied to the eradication of the disease. In this instance, through efficient management, the disease was not only confined to those municipalities which were infected before the arrival of the Bureau of Health agents, but was entirely eradicated, with only the loss of a few lives.

Owing to the disturbed conditions with regard to peace which have existed during the past three months in the Provinces of Samar and Leyte, it was not possible to remove the lepers from these provinces, as had been contemplated. It has therefore been decided to remove all the lepers from the Island of Panay, where there are supposed to be about 300. They are to be removed to the Culion Leper Colony before the first of November; thus another sorely afflicted island will be freed from this loathsome disease. In the islands from which the lepers have so far been removed it will be very interesting to note the frequency with which cases occur in the future.

Nothing further has been heard about the outbreak of cholera which occurred among the Moros in Mindanao, near Camp Vickars. The military authorities established a quarantine around the infected center, and it is presumed there has been no further spread of the disease.

In reporting the number of cases treated by Dr. Denier, the bacteriologist from the Saigon Pasteur Institute, it was inadvertently stated that he had treated eighteen cases, with a mortality of 74 per cent. On further investigation it was found that two of these eighteen cases were considered by him to be moribund, and he did not deem it advisable to inject any serum, so that the correct figures

should stand: Treated, sixteen cases, with nine deaths and seven recoveries, which gives a mortality of 56 per cent.

The "reorganization committee," which was appointed for the purpose of making recommendations to the Philippine Commission with a view to more economical administration, has made the following pertinent statement with regard to the present Civil Hospital: "The present Philippine Civil Hospital buildings and site are so expensive and unsatisfactory that your committee respectfully urges the immediate construction of the nucleus of a general hospital as a measure of economy as well as an essential to efficiency. The present rental charge is 12,000 pesos per annum, which, at the rate of the last bond issue, would be the interest on approximately 400,000 pesos. The number of employees now required by reason of the poor arrangement of wards would be able to care for a larger number of patients in a properly arranged establishment. The land immediately adjoining the grounds of the present hospital is so low and in such an unsanitary condition that, according to a recent survey, about 50,000 pesos would be required to make the location even tolerable. It is reported that inmates of the hospital have contracted diseases traceable to the conditions just described." However, this matter is now receiving careful attention, and plans and recommendations are actually before the Commission for action. It is believed that the necessary appropriations will be made in accordance with the recommendations of the reorganization committee.

Dr. E. R. Stitt, Commander, U.S.N., who has been engaged in special research work in the tropics, and more particularly in Manila, has been ordered to return to the United States Naval Medical School at Washington and resume his duties as instructor in that institution. Before going to Washington he will inspect the Naval Hospital at Yokohama and make such recommendations with regard to the installation of a modern system of sewage disposal as may seem to be desirable.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 1, 1906.

Dangers from Use of Lead Pipe in Water Systems.—Two cases are detailed by H. C. Baldwin. In both the lead poisoning followed the introduction of a municipal water supply. An epidemic of colic, indigestion, and debility broke out in the community, but the nature of the trouble was not recognized. It was found that the water acted on the pipe running from the street main to the houses. Both of the patients were young persons and showed a condition rarely appearing in adults, namely, a paralysis of the leg extensors as well as of the hands. The action of the water on the pipes has been found to be the carbonic acid present in different waters. This varies from time to time, so that a water safe to-day may be harmful at some future time. Ground waters contain as a rule more carbonic acid than do surface waters.

New York Medical Journal, November 3, 1906.

The Cold Wire Snare in the Removal of Faucial Tonsils.—H. P. Mosely advocates this method of tonsillectomy and exhibits a new snare (figured). He claims that with this instrument the tonsil can be removed as quickly as with the ordinary tonsillotome, and with but little more pain. Hemorrhage is practically absent. For flat tonsils the method is especially valuable. The snare presented has the merits of strength, easy application, and can be easily threaded.

The Possible Dissemination of Tubercle Bacilli by Insects.—S. E. Weber has made some observations along the line suggested by the title of his paper with reference to small forms of insects embraced in the Linnæan order of Neuroptera which are known as the psocidæ. These insects are found in abundance in barns and other buildings where animals are housed. On account of their habits it is evident that they are the intermediate hosts of some of the protozoa and other forms of parasitic life affecting the domestic animals. This forms one type of disease transmission. The other type is that in which the insect serves as a carrier only, and this is the form suggestive of the dissemination of tubercle bacilli. The psocidæ are, as their name implies, chewing insects, which fact differentiates them from the suctorial insects, and they fancy farinaceous food, for which reason they are found about the feed chests, granaries, and feed troughs or mangers of animals. It is to the atropedæ, a wingless subdivision of the psocidæ, or rather those species with rudimentary wings, which do not fly, that these researches are directed. The author figures in his paper some of the common forms of insect life which he thinks may serve as transmitters of the tubercle bacillus. These organisms are known as *Clothilla ocelloria, Lepinotus inquilinus* and *Dorypteryx pallida.* It is believed that some of these organisms consume the crusted admixture of saliva, sputa of infected cows, meal attached to feeding troughs, etc., and that they themselves become mixed up with the hay and grain fed to other animals; thus they may be the medium of conveying tubercle bacilli from one animal to another. Tubercle bacilli have actually been found in the stomach contents of the clothilla. In the dwellings of man the atropedæ may be found on starched goods in drawers, in bed clothing, generally in spare rooms, on books and papers, upon the walls and floors, on window curtains, and upon all kinds of clothing. The nymphs and mature forms of these species have been found on eatables, such as potatoes, onions, apples, pears, dried corn, beans, strawberries, raspberries, blackberries, and tomatoes. In fact, they may be found on anything which has been in a vehicle stored in some out building in the form of a basket, box, bag, or measure of capacity. Such articles often remain undisturbed until the season comes along, and the products mentioned are to be put on the market. It is at such a time that the author has often found these vehicles to contain the insects in abundance. This is the chief means through which they become attached to the food for human consumption. A further source of danger through which they may gain access to the food of man is from the granary conveyed through the wheat or any other grain that may be ground for flour. The process of cooking, however, obviates to a certain extent this means of dissemination. But the food is not the only means through which these insects may convey tubercle bacilli to man, for their habits prove that they are adapted to carry the contagion directly to wearing apparels from contaminated sources where they have been feeding.

Artificial Cycloplegia in Errors of Refraction.—The paper of M. L. Benoit is very largely a review of the work of Troncoso, who divides cycloplegics into three classes: First, those with slow effect, such as atropine and daturine; second, those whose effect passes with much rapidity, *e.g.* hyoscine; and third, those with a very brief effect, such as scopolamine and homotrapine. The authority referred to has published tables of 1,000 cases from private practice in which the refractive conditions have been studied with the utmost care. Concerning the choice of a cycloplegic Dr. Benoit says that of the first class, above referred to, the only one used is atropine, three instillations being made daily in the upper part of the cornea, holding the eyelids open and the lower one somewhat everted, pressing with the index finger the inferior lacrymal canal in order to prevent atropine from getting through the nasal duct in the nostrils, and by absorption producing toxic symptoms. In children also the use of atropine for five or six days is absolutely necessary to paralyze accommodation. Their loss of time from school should not be taken into account. In adults until forty-five years old the most used of the cycloplegics is homatropine in cumulative doses, which has the advantage of paralyzing the accommodation for forty-eight hours only. Its results, however, are not absolutely satisfactory in patients less than twenty-five years old and who may suffer from ocular fatigue due to overwork. In these cases one may use hyoscyamine, the effects of which last less time than those of atropine. This drug has the inconvenience, however, of varying in its effects, in which case we should prescribe the neutral salt, the solution to be filtered through paper. Scopolamine is a very light cycloplegic which can be used advantageously in a few cases, but it has the inconvenience of sometimes producing toxic symptoms, vertigo, dryness of the throat, etc. Duboisine presents the same disadvantages. Moreover, in the choice of a cycloplegic we must bear in mind the patient's age and occupation, and the form of ametropia present. Busy men have but little time to give up to these matters and the rapidly acting remedies must be employed.

A Rational Treatment of Habitual Constipation.—D. H. Murray thus describes his method. All anal lesions are corrected. The procedure referred to below is followed every fourth day until the bowels act without help. The patient is placed in the Sims position and an electrode after the Ewald pattern, with a perforated soft rubber shield, is passed into the sigmoid. The rectal electrode is connected with the posi-

tive pole, and rubber tubing also connects it with an irrigator filled with normal saline elevated about three and a half feet above the patient. The negative electrode is made of well-padded sheet lead and covered with a towel wrung out in hot normal saline. Thus we have an electric saline douche which quilts the intestinal mucosa and at the same time gives a stimulus to the muscular coat. The saline should flow very slowly and from ten to twelve minutes be devoted to this part of the treatment. From one to two quarts of fluid are thrown into the sigmoid and descending colon. The patient is then allowed to go to the toilet, where a free evacuation takes place, leaving the intestinal mucosa clean. After this the patient returns to the table for the last half of the treatment. This consists in throwing one ounce of an emulsion of olive oil (one pint), iodoform (one dram), bismuth subnitrate (two ounces) into the descending colon. This is followed by one to two ounces of some dilute astringent or antiseptic solution of hydrastis. The iodoform is omitted from the emulsion if the patient has an idiosyncrasy that would make its use unadvisable, but the author finds that the patients do better when using the iodoform. After throwing the medicament into the sigmoid, the patient is kept for about ten minutes on the table, so tipped that the hips are elevated considerably, allowing the emulsion to gravitate high up in the colon.

Journal of the American Medical Association, November 10, 1906.

Headache and Eyestrain.—G. M. Gould claims that a vast majority of all cases of headache, certainly nine-tenths, are due to eyestrain beyond question, and that with or without this headache a large indefinite proportion of digestive, nervous, and psychic disease is due to the same cause. He accuses the ophthalmologists of being in a state of narcotism on this subject, and textbook writers and medical instructors are, he thinks, almost criminally indifferent to the matter. The general practitioner in the country, and also in the cities to some extent, is far more alive to the truth than are the specialists. He says it is, of course, beneath the dignity of most neurologists to care about the cure or cause of any disease. He believes that the explanation of all this is the lack of skilled refraction work. Until we establish a serious and scientific refraction school the evil will continue, and where there are few skilful and careful refractionists in the country who would agree in their diagnosis in one case there are 5,000 who would disagree, root and branch. There are, he says, at least 15,000,000 American children and adults afflicted with lateral curvature of the spine, and this he attributes largely to unrecognized ocular defects. To this he attributes largely the growth and success of osteopathy, Eddyism, and other quackeries. The hope of progressive and helpful medicine, he claims, lies in the general and country practitioners, and until they secure the establishment of at least one serious refraction school with a two- or three-year obligatory course of post-graduate study the ophthalmologists will not agree.

Headache from Aural Disease.—P. Hammond says that headache from aural derangement is more likely to be misunderstood as to its cause than that from ocular trouble, notwithstanding its possible severity, because it is not so directly associated with conscious functional defect of the special sense, especially the chronic forms of aural headache. Yet it is fairly common, the more so because of the intimate relations of the innervation of the ear and the central nervous system. In young children, as Gradle has shown, a continuous headache is likely to occur from slight obstruction of the Eustachian tubes which is at once temporarily relieved by inflation of the middle ear. For permanent relief, steps should be taken to remove any adenoids or other causes of obstruction of the Eustachian tubes. In the more chronic adhesive processes in the internal ear, absolute pain is seldom felt, but there may be a feeling of fullness or of pressure in the brain. When headache is due to acute middle-ear inflammation it is usually relieved by paracentesis. Politzer thinks that some of the most severe cases are due to hyperemia transmitted to the scalp. Severe pain with aural disease, not confined to the region of the ear and resistant to treatment, suggests intracranial trouble. The most enduring types of headache are seen in old cases of chronic suppuration, in which masses of indurated products form in the cavities of the middle ear and mastoid. The pain is usually dull and heavy, but is subject to exacerbations which may be brought on by the use of injections, especially of hydrogen peroxide, which swell up the masses and cause pressure Caries also, especially with granulations, may be the cause of headache in these cases. The diagnosis can often be made by the discharge, but if the suppuration is slight or absent the most careful examination may be required. It is very common for an ear that has formerly suppurated to remain apparently dry for many years. Treatment should aim at removal of all diseased tissue. Sometimes this can be accomplished by introducing astringent and antiseptic solutions into the ear, but if bone caries is present it must be thoroughly removed. In advanced cases the radical mastoid operation may be necessary. In any event cessation of the discharge will probably relieve the headache.

Constitutional Headaches.—G. L. Walton discusses the headaches complained of by neurotic individuals, often presenting physical and mental degenerative stigmata, and which are resistant to treatment, although organic or toxic causes cannot be discovered. The correction of ocular or nasal defects or of uterine deviations, etc., is also negative as regards relief of the headache. It is, he thinks, perhaps not what a perfectly normal person would call a headache, but is rather a sort of uncomfortable sensation that has become so irksome by the focusing of the patient's attention on it that at last only such terms as agonizing or excruciating seem adequate to describe it. The sense of mental fatigue, for example, may be more acutely realized than by the ordinary individual, besides being really aggravated by the patient's inability to relax the mental activity. These patients are irritably sensitive and self-conscious, and the headache is only another sign of general degenerative deviation. The dividing line between this variety and the reflex headaches is perhaps not sharply drawn and there are doubtless many cases in which the two elements, constitutional and reflex, are so combined and interdependent as to make the distinction difficult. The treatment of constitutional headache is not very hopeful, since a cure demands an entire change in the patient's make-up, including susceptibility to fatigue. Walton advises the correction of ocular, nasal, and other defects to give the benefit of the doubt as to a possible reflex factor. It is well, he states, to build up the patient's general condition not only by medicines, but also by all other available means. If mental training can aid in the modification of the obsessive tendency, a step is made in the right direction.

Chronic Headache from Pelvic Disease.—F. E. Davenport, understanding by chronic headache, not a constant pain, but one recurring at more or less frequent intervals and of a uniform type, finds it not a very common complication of pelvic disease. In over 1,000 cases from his notebook, he finds it mentioned only ninety-eight times, or in about only 10 per cent. In about one-third of these the headache was associated with menstrual disorder, and the one abnormality constant in these cases is diminution in the amount of blood lost, either from scanty flow in the regular periods or from delayed menstruation. The headache usually comes on before the flow, lasts one or more days, and ceases with its appearance. It is evidently due to a pelvic congestion, manifesting itself by disturbances elsewhere, and the headache is one of these. He gives his conclusions as follows: 1. Chronic headache associated with pelvic disease is accidental, except when it is the most marked symptom of irregular or scanty menstruation. 2. In other pelvic disorders it is usually an expression of the neurasthenic condition of which the pelvic lesion is merely one factor or accessory predisposing cause. 3. Treatment for the first class of cases consists of general building up measures and local depletion. 4. Treatment of the second class consists in the rectification of existing local trouble unless specially contraindicated, but the main reliance is to be placed on prolonged and systematic treatment of the neurasthenia. He does not think that headache is a common symptom of other pelvic conditions. As a local depletory measure, when such is indicated, he says nothing is so simple in application and so efficient as the use of wool tampons soaked in glycerin. The profuse watery discharge they produce relieves the engorged vessels and equalizes the circulation.

Foreign Bodies in the Bronchi.—Emil Mayer reports five cases in each of which a foreign body was removed from the bronchi. In one case the patient, a child of five, died. In the diagnosis, in addition to the symptoms, Mayer advises the use of the Roentgen ray. In regard to the treatment he advises early operation unless there is some reason of great importance for delay. In very young children he prefers a tracheotomy to

direct bronchoscopy, as the operation is more quickly accomplished, and a much larger tube can be inserted, if necessary, in the larynx. As a result of his experience he concludes that: 1. The diagnosis may often be fully established by auscultation and percussion, and the use of Roentgen rays may not always be depended on. 2. Solid bodies producing occlusion should be operated on immediately. 3. Tracheotomy affords by far the best chance for the patient. 4. The public, as well as the profession, is in great debt to Professor Killian for his valuable instruments and his work on "Bronchoscopy," resulting in the saving of many lives that otherwise would have been lost.

The Lancet, October 27, 1906.

Cases Treated by the Injection of Bacterial Vaccines.—A series of thirty-four cases is reported by E. Turton and A. Parkin. Their results are, on the whole, favorable and they think that there is a great future for this plan of treatment. They admit some failures, but they have also scored some notable successes, particularly in two cases of *Bacillus coli communis* infection. Broadly speaking, they find that acute cases are the more difficult to cure, because there may not be time enough to raise the opsonic power to such a degree as to influence the course of the disease; and at present we do not know much about the proper dosage necessary to do the greatest amount of good without doing evil—*i.e.* producing a dangerous negative phase. Nor is it possible to cure a case of fifteen years' chronicity in a like number of weeks. They have not used the injections in any haphazard sort of way, but only after careful estimation of the result of each injection at the beginning of the treatment. Later, when it is found from a study of the opsonic chart how long the result of each injection lasts—what might be termed the periodicity or opsonic wave—then the estimations can be made less frequently and the injections continued with certainty.

An Unusual Case of Thrombosis of the Lower Part of the Lateral Sinus, of Aural Origin.—The patient of A. Bronner was a healthy boy of fourteen years with an aural discharge for some years and mastoid pain for several days before coming under observation. The symptoms remitted, but on the tenth day of observation it was deemed necessary to operate. Some pus was found in the mastoid cells, but the lateral sinus was apparently quite normal, the dura was not thickened, and there was no thrombosis. Rigors recurred and crepitation over one lung, and the wound was reopened on the third day. The dura appeared quite normal, there was no extradural abscess, and the sinus was not thrombosed. An incision was made into the sinus and there was a sudden gush of blood, which was difficult to control. There was no swelling or tenderness over the jugular vein. There was no papillitis, although the disks were rather congested. Both lungs became involved and there were signs of commencing endocarditis. The cerebellum was explored with negative results. The boy died on the seventeenth day. The postmortem examination showed a small purulent clot in the jugular bulb. The lateral sinus itself was not thrombosed and the walls were nearly normal, with perhaps some thickening in the lower part. The author notes the following points of interest in the case: There never was any swelling or tenderness over the mastoid or over the jugular vein. The walls of the lateral sinus were practically normal and the thrombosis was situated low down in the bulb of the jugular. We should, in all similar cases, not only examine the upper part of the lateral sinus, but also the lower part as far down as the bulb of the jugular. The sinus may be apparently normal and the thrombosis be situated lower down. In fact, the author thinks we should always, in cases of mastoid disease with recurrent rigors, ligature the jugular, even if we cannot find any definite lesions in the vein. The walls may be diseased over a very small area and a small septic clot form there, which would give rise to septic disease of the lungs. Had the jugular been tied early in this case the boy's life would probably have been saved.

Pericarditis Following Head Injury: Paracentesis.—J. Gillan reports the case of a boy of sixteen years who was thrown against a rapidly revolving wheel and sustained a severe lacerated wound of the neck and mastoid region. After the separation of the sloughs the soft tissues did well, but a layer of dead bone remained in the mastoid groove. Evidences of sepsis within the skull appeared. The sequestrum came away later, but evidences of pericardial infection became evident. On the seventh day paracentesis of the pericardial sac was done, and from that time on the progress of the case was steadily toward recovery. Attention is called by the author to the following points of interest: (1) The great and immediate relief obtained by the removal of a relatively small quantity of fluid. The actual quantity removed was six ounces six drams, and, considering the extent of the dull area and the small impression made on it by the withdrawal of this quantity, it is obvious that the amount of fluid remaining must have been very large compared with what was withdrawn. (2) The rapid absorption of the remaining fluid. (3) The fact that a pericarditis, presumably the result of a septic process, should pass off so quickly and completely without the formation of pus within the pericardium. The other common causes of pericarditis could be excluded in this case. There was no Bright's disease. There was no other indication of rheumatism, nor was there a rheumatic family history.

British Medical Journal, October 27, 1906.

Perforation of the Colon in Hemorrhagic Typhoid.—In a patient (young male) of E. S. Molyneux, taken suddenly ill, a diagnosis was made of pneumonia. Inside of twenty-four hours the symptoms suggested perforation of some hollow viscus. Operation was refused. Death resulted in six days from the first symptoms. Autopsy showed bronchopneumonia present at both bases. The Peyer's patches in the ileum were much swollen, especially those close to the cecum. Some showed sloughs. In other cases the sloughs had separated. In the ascending colon the solitary follicles were enlarged. A small, round perforation was found in the ascending colon, close to the hepatic flexure. There were many hemorrhages into the walls of the small intestine. A large extraperitoneal hematoma was found under the upper part of the left rectus; there were some smaller hemorrhages into the right rectus.

Nitrite of Amyl in Post-Partum Hemorrhage.—J. R. Keith reports a case successfully treated. The patient, a 4-para of thirty-three years, had suffered from hemorrhages at previous labors and had been debilitated during her last pregnancy. All went well in the labor until the extraction of the placenta, when profuse flooding commenced. This was, however, almost immediately arrested by the inhalation of a capsule of nitrite of amyl. After a hot saline infusion of two pints per rectum the pulse, which had run up to 120, soon improved, and in less than an hour was 86. No further trouble followed.

The Bacterioscopic Analysis of Excremental Pollution.—E. Klein declares that in judging of this form of excremental pollution, our attention should be particularly directed to the *Bacillus coli communis*. One of the principal differential characters of this organism is its power to ferment lactose. The special medium used for its growth is a mixture of sodium taurocholate, peptone, glucose, litmus, and water. Both the *Bacillus coli* and the *Bacillus typhosus* grow well in this taurocholate broth, making it uniformly turbid in twenty-four hours at 37° C.; but if *Bacillus coli communis* be present, on slightly shaking the tube copious evolution of minute gas bubbles will be noticed on inspection with a hand lens. In a large number of tests made with this medium Klein has invariably found that if after twenty-four to forty-eight hours' incubation the tubes show marked turbidity, and on slight shaking show copious evolution of gas bubbles, one can be certain that *Bacillus coli communis* is present. This taurocholate broth has one further advantage; it is this: While it allows the growth of fecal streptococci it inhibits some other streptococci. He has made experiments with streptococcus directly isolated from human fecal matter by Drigalski-Conradi plates, with streptococcus of saliva and with *Streptococcus pyogenes*, and he has found that while the streptococcus of human feces grows well in the taurocholate broth—at 37° C. it produces in forty-eight hours copious growth in the form of granules and flocculi with slight general turbidity of the broth—the others (streptococcus of saliva, *Streptococcus pyogenes*) produce no growth, the broth remaining perfectly clear.

Some Principles of the Treatment of Fractures.—J. E. Bowser notes that there are two important features introduced into the modern treatment of fractures. First, the early employment of massage and movement, and second, the application of operative measures to ordinary cases of simple fractures. The use of the *x*-rays has also introduced new factors. He discusses especially the first of these topics, tracing the development of the giving up of the old traditional ideas of immobilization by rigid apparatus. He lays down the general principle that absolute immobility is not essential to bony repair. This is shown in the repair of fractured ribs. The modern method reduces the danger of wasted muscles, stiff joints, weak limbs, and pain on attempted movement. The massage to be advised in fracture cases differs entirely from that

of the professional masseurs. It consists in a soft, smooth, uniform, above all painless, mobile pressure in the direction of the venous current. At first little more than a caress, the degree of pressure is progressively increased so as to act gradually upon the deeper structures. Ordinarily, massage is practised from the very beginning of the treatment, and repeated daily in *séances* of half an hour's duration. Massage prepares the way for movement. After massage, passive movements of the joints, which before had been impossible on account of the pain that they caused, become surprisingly easy. They are, therefore, always practised at the end of the *séance* of massage. These movements, whether passive or active, are necessarily of slight extent, being limited by two imperative conditions: First, they must be painless, and second they must not cause new displacements of the bony fragments. As a result of these movements, pain is relieved, muscular spasm is relaxed, and swelling is reduced. Adhesions are prevented. Massage shortens the duration of treatment. The chief factor is the condition of the nerves, muscles, and joints of the limb at the moment when bony union is complete. Instead of being crippled by immobilization, they are fit and ready for immediate use. It is estimated that the time that requires to elapse before a patient is permitted to resume his ordinary occupation is diminished by at least one-third.

Hospital Treatment of Curable Cases of Mental Disorder.—E. Goodall does not think it right from a scientific standpoint to exclude one kind of illness, viz., mental disease, from participation in the benefits of the system which has been organized for the treatment of all other forms of sickness and under which cases of disease and injury which offer prospects of cure and alleviation are received into hospitals. He advocates the establishment of a hospital for curable cases of mental disease and elaborates the plan on which he thinks it should be conducted. He has also come to the conclusion that it is time an attempt was made to arouse public opinion to the importance of putting into force the procedure of forbidding under severe penalties the marriage of persons released from asylums, and he believes that like penalties should be inflicted in all cases in which the responsibility for illegitimate procreation among this class of persons can be fixed.

Berliner klinische Wochenschrift, October 22, 1906.

Poisoning by Oil of Sesame.—Rautenberg says that last year he observed six cases of peculiar toxic symptoms following the use of oil of sesame as a rectal injection, a third to a half a liter being given. These patients for the most part manifested prostration, coldness of the extremities, and marked cyanosis of the face and limbs. The condition lasted for twelve to thirty-six hours, and although the presence of methemoglobin in the blood was suspected, it was impossible to demonstrate the spectrum of this substance either in the blood or urine. The author has just had another instance of the same sort, in which 400 c.c. of the oil were given. In this case the symptoms were more severe than in the preceding ones and unconsciousness, fixed pupils, pulmonary edema, and respiratory failure resulted. It was only with difficulty that the patient could be resuscitated, and the author was able to demonstrate the characteristic absorption band of methemoglobin in the blood spectrum, and methemoglobinuria was also present. The author was unable to discover the reason for the production of this serious form of intoxication by the sesame oil, but states that he believes that it was due to some commercial adulteration, and emphasizes the necessity for care in employing a new supply for the first time. The oil that was used last year and that which caused the symptoms in the present case were obtained from two different sources.

Münchener medizinische Wochenschrift, October 23, 1906.

Acute Intestinal Tuberculosis in Adults.—Passler states that tuberculous infection of the intestinal tract may occur in adults independently of involvement of the lungs or other organs, and may go on as a clinical entity with febrile course leading to death in a few weeks. He describes two cases of this rather unusual condition, one in a man of forty-four years and the other in a woman of about the same age. In each instance pulmonary symptoms were almost or entirely absent and the diagnosis remained doubtful until the time of death. In both of these cases a few staphylococci were discovered in the blood, and the author suggests that the association of pus organisms with the tuberculous infection may have something to do with the severe course in such cases, just as takes place in pulmonary tuberculosis. As no tubercle bacilli can be found in the sputum in these cases, the author advises that in grave febrile disorders that present difficulties in diagnosis the stools also should be examined for tubercle bacilli.

Deutsche medizinische Wochenschrift, October 25, 1906.

The Helmholtz Treatment of Hay Fever.—Boesser endeavors to rehabilitate in a somewhat modified form a treatment of hay fever said to have been employed with good results by Helmholtz on his own person. Boesser uses a 1 per cent. solution of a double salt of caffein consisting of two parts of hydrochlorate of quinine and one part of pure caffein. Whereas the hydrochlorate of quinine is soluble only in thirty-four parts of water, the caffein salt is soluble in equal parts of slightly warm water. As soon as the patient notices the first evidence of the onset of an attack a few drops of the solution are dropped into the conjunctival sac and the patient lies down for a few minutes, during which time moderate or severe burning is felt in the eye with increased secretion of tears. These wash the remedial solution through the tear duct into the nasal passages and over all the mucous membrane from which the reflex symptoms of hay fever can originate. The ocular irritation subsides in a few minutes, the attack is aborted, and the effect is said to persist from four to six hours.

Experimental Observations on the Behavior of Bacteria in the Large Intestine.—Rolly describes a series of experiments which lead him to the belief that the large intestine is capable through its own activity, partly through elimination, and partly perhaps through direct destruction, to dispose of any foreign bacteria that may enter it, and to restore the floral normal to the colon. On the other hand, this process was greatly impeded when the mucosa was damaged by the injection of acids or alkalies, and it appears that the normal activity of the mucous membrane plays a large part in the bacterial content of the gut. Disease of the mucosa alone is therefore sufficient to permit an excessive proliferation of microorganisms.

French and Italian Journals.

Eighty-five Gynecological Operations by the Abdominal Route.—Bégouin reports eighty-five major gynecological operations by the abdominal route without one death. Of these twenty-six were ovariotomies, thirteen were ovariosalpingectomies, and forty-six were hysterectomies. The writer attributes most of his success to the fact that he has laid great stress upon the necessity of increasing the resistance of the patient before operation, especially in the cases of uterine cancer and hemorrhagic fibromatous growths. After the operation he has made use of serum and spartein if the heart was weak. He has also taken great care in the disinfection of the vagina, using cyanide of mercury and peroxide of hydrogen for this purpose for several days preceding the operation. This seemed especially essential in the cases of carcinoma.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux,* September 23, 1906.

Ovarian Cyst with Sarcomatous Degeneration.—J. Abadie and X. Bender report this case. The patient, a woman forty-four years old, had had three abortions. The last abortion occurred four years before the patient's entrance to the hospital. The first appearance of the tumor was noted one year after the last abortion. Pain had increased gradually, the most severe paroxysms being felt in the right iliac fossa. The tumor was very large and seemed to be divided into two parts. Ascites was marked. Laparotomy revealed a polycystic growth. It was divided into several parts by partitions of very resistant fibrous tissue. Adhesions to the surrounding tissues were numerous. The patient died three months later. Microscopical examination of the neoplasm showed it to be a multilocular cyst which had undergone sarcomatous degeneration. Peritoneal metastases were noted.—*Annales de Gynécologie et D'Obstetrique,* September, 1906.

Action of X-Rays on Tuberculous Adenopathies.—Giuseppe Caccia and Carlo Francioni have used the *x*-rays in four cases of tuberculous glands of the cervical region, the glands in one of them being of enormous size. This patient was a baby of five months of age, and the glands were of such size as to give rise to a possible diagnosis of lymphosarcoma, although it was finally decided to be atypical lymphatic enlargement of tuberculous nature. After the first application the glands diminished in size and continued to diminish until they had disappeared. At the same time the glands of the opposite side of the neck had become enlarged, and the child had fever and was in failing health. The spleen had also become enlarged. A fatal result ensued after some months. The autopsy showed the glands to be tuberculous, and the infection had extended to the intestines, mesenteric glands, and spleen. The remaining three cases were not at all benefited by the treatment. The conclusion arrived at is that radiotherapy is valueless in tuberculous adenitis of the ordinary type, but that it is of value in the lymphomatous type.—*Rivista Critica di Clinica Pediatrica,* September, 1906.

Book Reviews.

CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL, INCLUDING THE CHEMISTRY OF THE U.S. PHARMACOPŒIA, A Manual of the Science of Chemistry and its Application to Medicine and Pharmacy. By JOHN ATTFIELD, F.R.S., M.A., Ph.D., F.C.S., etc., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. New (19th) edition, specially revised by the Author to accord with the New U. S. Pharmacopœia, edited by LEONARD DOBBIN, Ph.D., F.I.C., etc., Lecturer on Chemistry in the University of Edinburgh, etc. 12mo, 760 pages, illustrated. Philadelphia and New York: Lea Brothers and Company, 1906.

A BOOK which has reached its nineteenth edition may be judged to have proved itself worthy of the confidence of that class for which it was written—in this case students of medicine and pharmacy. The reason for this popularity is manifest to one who merely looks through the book, reading a paragraph here and there, and much more to the student who takes it as his guide. The author has the faculty, which so many teachers and writers of text-books unfortunately lack, of keeping himself always at the student's level, leading him along gradually from the easy to the more difficult, explaining each step as he goes along, and never taking for granted that the student knows anything which has not yet been told him. At the beginning of each section there is a paragraph of "advice to students," showing them how they can, with the greatest profit to themselves, go through the succeeding pages, what part is to be simply read, and what part studied with care; and throughout the directions are so clear that any person of ordinary ability can, with this book as his only guide, and without the aid of a teacher, obtain a grounding in chemistry sufficient, and more than sufficient, for his needs as a physician or pharmacist. We would commend the page at the beginning of the work, on "Advice to Students Respecting Their Object in Studying," not only to students of chemistry, but to all students of whatever subject. The author here warns against studying merely by way of preparation for examination, for this, he says, is to mistake the means for the end. The object of study is to fit oneself for one's position in the world, and the student should therefore work diligently, study thoughtfully and deliberately, and, above all, be thorough. The end and aim of the study should be to acquire an education—this done, the examination will take care of itself. The student who will conscientiously use this book in the manner pointed out by the author cannot fail to acquire a knowledge of the essentials of chemistry that will not only carry him through any examination to which he may be subjected, but will remain by him as a possession for life.

LA MÉLANCHOLIE. Étude Médicale et Psychologique. Par RENÉ MASSELON, Médecin-adjoint de l'asile de Clermont de l'Oise. Ouvrage couronné par l'Académie de Médecine. Paris: Félix Alcan, 1906.

MASSELON offers in this little volume an analytical study of melancholia, which he regards not as a form of insanity, a disease *per se*, but as a syndrome which should be known as "the melancholic state." According to Kraepelin, melancholia is a disease of the presenile state, "which is the morbid expression of the feeling of increasing helplessness which seizes old people." Masselon, however, looks upon "pure, essential" melancholia in the manner of Joffroy, namely, as a syndrome which may occur as the result of a variety of morbid states (p. 258). It is not only more the result of senile involution than of tuberculosis, the puerperal state, etc., but is the result of two factors, a predisposed brain and an organic state which induces a lowered vitality. Masselon's monograph makes interesting reading, though his conclusions may not be accepted by every authority.

OPERATIVE GYNECOLOGY. By HOWARD A. KELLY, A.B., M.D., LL.D., F.R.C.S. (Hon. Edinb.), Professor of Gynecological Surgery in the Johns Hopkins University, and Gynecologist to the Johns Hopkins Hospital, Baltimore, etc., etc. With Eleven Plates and Seven Hundred and Three Original Illustrations for the most part. By MAX BRÖDEL, Associate Professor of Art Applied to Medicine in the Johns Hopkins University. Second Edition. Revised and Enlarged. Volume I., Volume II. New York and London: D. Appleton and Company, 1906.

DURING the nine years that have elapsed since the appearance of the first edition of Professor Kelly's remarkable work gynecological practice has seen many changes more or less sweeping in character. For the most part, however, these were foreshadowed in the original "Operative Gynecology," and in many instances, such, for example, as in the cystoscopy of the female bladder and the diagnosis of ureteral and pelvic calculi, they were the outcome of methods devised or elaborated by Kelly. In the present revision of his treatise the author, therefore, has not been obliged materially to alter his standpoint in any respect or to chronicle any radically new departures. In spite of this, the new work contains much fresh matter, and particularly it surpasses its predecessor in its illustrations, of which two hundred have been added. The inimitable drawings prepared by Professor Brödel for the first edition set a new standard for the illustration of medical books, and though his work has served as a salutory stimulus to other artists in this field, there is no doubt that these two volumes still stand alone, as examples of the best in art as applied to medicine. In the first volume the most important changes are found in the chapters on topographical anatomy, which has been enlarged, and in the discussion of perineal lacerations, which includes several new procedures for the repair of tears extending through the sphincter. The sections in diseases of the urinary system have also been amplified, and stress is laid on the technique of irrigating the renal pelves. The requirements of office gynecology have been met by the introduction of new matter in local and palliative treatments, uterine displacements and pessaries, and on menstruation and its anomalies. Dr. W. W. Ford has written a new chapter on bacteriology, and a section on the use of the *x*-ray in the diagnosis of renal calculi is contributed by Dr. F. H. Baetjer. The diseases of the hymen are discussed by Dr. George Gellhorn, and the chapter on inversion of the uterus has been rewritten by Dr. G. W. Dobbin. Changes have also been made in the chapter on the Bartholinian glands which have been brought into conformity with the recent work of Dr. T. S. Cullen, and a chapter on anesthesia has been contributed by Dr. H. W. Cook. In the second volume a new chapter on abdominal extirpation of the cancerous uterus with over fifty new illustrations is the work of Dr. John A. Sampson, and a new chapter on gynecological diseases in children has been written by Dr. Elizabeth Hurdon. Kelly considers that experience has shown that the objections made to the operation of ventral suspension are unfounded, but he now also describes, though without comment, Gilliam's operation of implanting the round ligaments in the abdominal wall. In the preface the author also refers to a description of the Alexander operation said to have been added, but a search of the index and table of contents fails to reveal this title. In the chapter on anesthesia brief mention is made of the value of blood pressure determinations in connection with operations, but the importance of determining the patient's condition by systematic observations during the course of severe operations or of using this method of judging how far it is wise to go when a series of operations is contemplated on the same patient at one sitting, is not brought out. The work has been improved where improvement was possible, and is no doubt destined long to maintain its preeminent position in gynecological literature.

OBSTETRICS. Vol. V of The Practical Medicine Series, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of GUSTAVUS P. HEAD, M.D.; Vol. V., edited by JOSEPH B. DE LEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School. With the collaboration of D. ROEHLER, M.D., and HERBERT M. STOWE, M.D. Series 1906. Chicago: The Year Book Publishers, 1906.

THE editor of this volume of The Practical Medicine Series has commendably kept in mind the object of the book and has included a fuller discussion of the purely practical phases of obstetrics, summing up briefly those of scientific interest. The book is thoroughly up to date, and the editor has greatly increased its value by his bracketed comments. The chapters on Eclampsia and on Operative Obstetrics are especially valuable as summaries of current work in these two fields.

THE SCHOTT METHODS OF THE TREATMENT OF CHRONIC DISEASES OF THE HEART. With an Account of the Nauheim Baths and of the Therapeutic Exercises. Illustrated. By W. BEZLY THORNE, M.D., M.R.C.P. Fifth Edition. Philadelphia: P. Blakiston's Son & Co., 1906.

THE fact that five editions of this work within eleven years have been issued, vouches for the increasing interest of the profession in methods not purely medicinal. The author cites cases and gives sphygmographic tracings, proving beyond a doubt the value of the methods made famous by Schott of Nauheim. In the present edition there have been few changes. However, the writer asserts strongly that after his latest experiences with the treatment he can prove that in aortic regurgitation we can administer the baths and the movements with safety and exceptionally good results, and that they are of marked benefit in cases of Raynaud's disease and exophthalmic goiter.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held November 1, 1906.

THE PRESIDENT, DR. CHARLES L. DANA, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Ophthalmology. After the nomination of officers to serve during the ensuing year the scientific work began.

Report of the Committee on the Relief of the Medical Profession in San Francisco.—The President reported that, besides the $5,000 given by the Chamber of Commerce, 440 men had subscribed $5,791.10 and over thirteen medical societies had donated $1,990. Of this amount $7,474.58 had been sent to San Francisco. The report was approved and the committee discharged.

Demonstration of the Various Recently-Devised Electric Ophthalmoscopes, which Facilitate Ophthalmoscopy for the General Practitioner.—Dr. J. HERBERT CLAIBORNE made this demonstration.

Drs. PIFFARD, POOLEY, LESZYNSKY, ROOSA, GRUENING, AND DANA discussed these instruments.

Choroidal Diseases in Their Relation to General Diseases, and Particularly to General Infections, as Well as Autointoxications.—**Dr. G. E. DE SCHWEINITZ** of Philadelphia presented this paper. He said that the classification of choroidal disease was very unsatisfactory. Textbooks divided choroiditis into superficial and deep, and placed most forms in the suppurative or the nonsuppurative choroiditis. Dr. de Schweinitz suggested the following: (1) Choroiditis dependent upon specific infectious diseases; (2) choroiditis dependent upon diseases of definite organs, as of the liver and kidney; (3) choroiditis dependent upon diseases of the blood, notably the various anemias; (4) choroiditis dependent upon diseases of nutrition, gout, arthritis deformans, etc.; (5) choroiditis dependent upon intoxications, autointoxications, etc.; (6) choroiditis dependent upon diseases of the tonsillar tissues and sinuses. Basing choroiditis upon the ophthalmoscopic appearances, he had observed the following types: (1) Localized exudative choroiditis; (2) diffuse exudative choroiditis; (3) disseminated choroiditis; (4) serpiginous choroiditis; (5) the various types of simple choroiditis. Anomalous forms were met with in great number. In considering choroiditis dependent upon specific infectious disease, first stood syphilis, the lesions appearing first as a chorioretinitis, the retina being secondarily involved. In the acquired form the disease appeared from one to three years after infection. Syphilis gave rise to the disseminated form of choroiditis, but this was not pathognomonic in any sense of the term. It should be looked upon as a late manifestation, and might affect the choroid in a diffuse manner. This depended upon the infiltration of the choroid by the toxins of syphilis; the disseminated and circumscribed forms of the disease depended upon local deposits of the toxins of syphilis. Next to syphilis in importance he placed tuberculosis, and many cases of plastic choroiditis were due to tuberculosis. Many cases of disseminated choroiditis had been injudiciously treated by mercurials when tuberculosis was the cause. Besides syphilis and tuberculosis he discussed influenza, certain fevers, notably typhoid, and relapsing, when a localized exudative choroiditis was most frequently encountered, and croupous pneumonia. Dr. de Schweinitz concluded his paper by stating (1) that while syphilis was the most frequent cause of the forms of choroiditis dependent upon specific infections, it was not an exclusive one; there were tuberculosis and other specific infections, as diphtheria, influenza, and pneumonia; (2) while there was no known type of choroiditis pathognomonic of disease of single organs, it was not unlikely to affect the blood; (3) much evidence had been accumulated to show that certain affections, as ptomaine poisoning, as enterogenous autointoxications, must be given a definite etiology in choroiditis; many cases of choroiditis were dependent upon infection occurring through the tonsillar tissues; (4) each case of choroiditis not syphilitic in origin should receive careful study, including a searching examination especially of the secretions of the body, the intestinal tract in particular.

The Autointoxications.—Dr. E. E. SMITH, in presenting this subject, did not think that it was desirable to attempt any final classification of the various intoxications. He restricted his attention to the toxemias resulting from the formation of toxic substances within the body in other than specific infections, and distinguished the toxemias that resulted from the presence of an excess of physiological products and those toxemias resulting from products whose formation, though possibly tolerated in health, was not strictly physiological and which he termed pathological. He did not include systemic conditions dependent merely on the absence of a sufficient quantity of physiological products, as myxedema and cretinism. Many substances that in relatively small quantities were tolerated by the body without the production of any harm would in relatively large quantities produce such an inhibition of normal metabolism as to constitute an injury. Physiological products in sufficient amounts were sometimes toxic, and such physiological products were considered as waste products and products adapted to serve some purpose in the economy. In speaking of the waste products of the different excretory organs, he called attention to the fact that autointoxication by the products excreted through the lungs was accompanied by a deficient oxygen supply, but that the autotoxic factor was probably quite as responsible as the oxygen deficiency. The chief toxic factors here were carbon dioxide and the ammonium salts. The chemical substance responsible for the autointoxication resulting from renal insufficiency was not definitely determined. Experimental studies had made it evident that the toxicity of the urinary constituents was due to the salts of potassium and ammonium which gave to the urine more than three-quarters of its toxicity. These studies had failed to explain the uremic state, and we would have to look to disturbances in the physical condition of the protoplasm of the body cells for a part of the explanation of the uremic state. There was no established experimental proof that uric acid was toxic. Recent studies of nuclein metabolism indicated that the series of changes that began with nuclein breakdown and ended with uric acid destruction in the body were due to the activities of a considerable number of tissue enzymes or ferments. The uricolytic or destructive enzyme of uric acid existed chiefly in the liver and kidneys. In the toxemias of gastrointestinal origin there was retardation of hepatic function, and therefore the uric acid destruction normally accomplished by the liver was likewise retarded, and in consequence some uric acid escaped destruction and increased the amount eliminated. Regarding the purin bases, experimental study had shown that they were rather more capable of producing general toxic symptoms when injected into small animals than uric acid. On the other hand, there was no reason at present for believing that they gave rise to systemic intoxication in any diseased conditions. What was true of the toxicity of the purin bodies was also true of the hexane bases and other leucomaines. The toxic element in exophthalmic goiter had been attributed to the overproduction of the iodine products of the hyperemic thyroid, but we were not yet justified in regarding it as unequivocally established. Evidence had been obtained which seemed to indicate that sunstroke was accompanied by the development of autointoxication; but whether the products were physiological or pathological was not known. In considering the autointoxications due to pathological products, he referred to the products of degeneration of the nervous system, to acid intoxication, the toxemias of pregnancy, and gastrointestinal intoxication. The nervous

system participated in many systemic intoxications, the changes being of the same character and for the same reason as hepatic or renal parenchymatous degeneration. The nervous system might itself originate a toxic condition, as shown in general paralysis of the insane. The term acid intoxication signified that profound acidosis which was the cause of diabetic coma and less frequently of other active manifestations, notably persistent acid vomiting. The acid formed was chiefly betaoxybutyric acid. When the acid production reached an active point it constituted a profound toxic condition, and one should not neglect to consider its presence in the graver manifestations of diabetes mellitus, and also in any case of persistent acid vomiting, either in childhood or in adults, or in pregnancy. The toxemia of pregnancy was closely allied to acid intoxication; but the urine showed in addition marked relative increase of the aminointegers, indicating hepatic autolytic changes. The reader of the paper considered the toxemias of gastrointestinal origin at length. He discussed the secretion and action of the various digestive agents, and also the normal bacterial flora of the gastrointestinal tract. He was of the opinion that, notwithstanding the discovery that the colon bacillus had a strong inhibiting action on the growth of putrefactive organisms and that its function was probably a protective one, that we were warranted in concluding that it might not in itself be injurious by overabundance in the intestinal tract. He said the test for indican was so generally made use of that it was well to emphasize the limitations of its usefulness. It was only one product of intestinal putrefaction. There might be marked intestinal toxemia without excessive indol absorption. The other urinary products were skatoxyl, the phenols, the aromatic oxyacids, and the relative amount of sulphate in ethereal combination with these products. In this connection the condition of oxaluria should also be considered. Whether we had to deal with headache, lumbago, a cutaneous affection, an epileptic seizure, neurasthenia, or intestinal colic, the presence of a gastrointestinal toxemia might play a part, and should be given due consideration.

Drs. Charles J. Kipp of Newark, Charles S. Bull, and Hiram Woods of Baltimore, and others entered into the discussion.

Dr. G. E. de Schweinitz closed the discussion.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 25, 1906.

Dr. Arnold Sturmdorf in the Chair.

Presentation of Specimen of Pus Tube.—Dr. C. Clarence Sichel presented this specimen. The patient, 22 years old, eleven years ago was admitted to Mt. Sinai Hospital with a diagnosis of a left pyosalpinx. She was not operated upon at that time. Apparently there were no symptoms during the ensuing eleven years. At the end of this time she was brought to the hospital with a temperature of 102.5°, pulse corresponding, abdomen distended and tympanitic, tense and rigid. Her general condition was pretty good. The abdomen was opened in the median line and a large quantity of free pus was found under the incision. The tube was adherent and prolapsed into the pouch of Douglas, bound down by adhesions of all kinds. The tube was removed and drainage instituted in Douglas' pouch. An uneventful recovery followed.

Report of a Case of Spontaneous Rupture of the Cord, Intrapartum, With the Birth of a Living Child.—Dr. S. Marx said these cases were so exceedingly rare that he never saw one before, with the possible exception of one seen ten years ago; in this case, however, the fetus was born dead. The microscopical examination of the tissues at the site of rupture revealed a gumma of the cord. In the case reported there was no specific history. The patient was 39 years old, a primipara, and had been in labor several hours. There was an alternate dilatation and shutting of the cervix and an advancement and recession of the head with each pain. A presumable diagnosis was made of a short cord. Axis traction was made and a central laceration of the perineum resulted. A rapid delivery of the child was done, the only thing to do to save the baby's life. The cord was around the neck and was totally detached about one foot from the placenta. It required a long time to resuscitate the child. The placenta was expressed. Great difficulty was experienced in locating the stump of the cord where it was inserted into the placenta.

Description with Stereopticon Views of Special Features of the New Woman's Hospital.—Dr. LeRoy Broun gave this lantern slide demonstration.

General Discussion on the Pyelitis of Pregnancy.—Dr. Edwin B. Cragin opened the discussion. He said there were two forms of infection of the kidney and ureter which might occur in pregnancy or the puerperium; one, where the kidney substance was involved; the other, the pelvis of the kidney and the ureter. The latter form was generally meant when one spoke of the pyelitis of pregnancy. Up to 1904 the best literature on this subject emanated from the French. Since that time over one hundred cases had been reported in this country. The first description of the pyelitis of pregnancy appeared in 1841. The etiology and pathology, as we understood it to-day, was brought out in 1892, *i.e.* that the condition was due to compression of the ureter and infection of the ureter above that point. It was well known that when a kidney had been bruised in any way it was more likely to become infected. As to the frequency of the condition, he said it certainly was not an infrequent complication. During six years he had had twenty-five cases under observation, nineteen antepartum, and six postpartum. In considering the pathology, compression of the ureter, and infection above that point, he said that it was found in a large percentage of the ureters of pregnant women, that they dilated on one side owing to pressure of the pregnant uterus. Out of thirty-four autopsies on pregnant women by Ohlshausen there were twenty-five in which the ureters were dilated on one side or the other. Another authority had reported sixteen autopsies on pregnant women, in nine of which the ureters were dilated. In two cases seen at the Sloan Maternity a marked dilatation of the ureters was found. Therefore, he did not believe this condition to be so uncommon in pregnancy; it was not at all uncommon to have the ureter dilated on one or the other side, or on both sides. It was more often dilated on the right side, and there were three plausible reasons for this. In the first place the uterus naturally rotated to the right and forward; secondly, the right common iliac artery was more prominent than the left; thirdly, if one examined the urine of a typhoid fever case the typhoid bacillus would be found in the urine and with little injury to the urinary canal, provided there was no constriction; but it had been proven that if a sterile ligature be placed about the ureter and a hypodermic injection of streptococci or the colon bacilli be given, very often a streptococcic or colon bacilli infection would be started in the kidney, *i.e.* above the point of ligature. Thus, constricting the ureter made it more likely to become infected than one that was not. During pregnancy the ureter was compressed; therefore, there was more cause for infection occurring than would exist under ordinary circumstances; and so there was a greater frequency of infection of the urinary tract during pregnancy. With regard to the symptomatology, the condition was more frequently met with from the fifth to the eighth month of pregnancy. Occasionally the condition came on insidiously with but little temperature; as a rule, however, it was ushered in suddenly, with a sudden rise of temperature, perhaps with rigor, with pain and tenderness in the right kidney, and pus would be found in the urine; if examined
